

SWITCHING ROOK POLYNOMIALS OF COLLECTIONS OF CELLS: PALINDROMICITY AND DOMINO-STABILITY

FRANCESCO NAVARRA, AYESHA ASLOOB QURESHI, AND GIANCARLO RINALDO

ABSTRACT. The rook polynomial is a generating function that enumerates the number of ways to place rooks, with no two in the same row or column, on a collection of cells regarded as a pruned chessboard. In combinatorial commutative algebra, special attention is devoted to its variant, the *switching rook polynomial*, which is conjectured to coincide with the h -polynomial of the K -algebra associated with the given collection of cells. In this context, palindromicity plays a crucial role, as it reflects the algebraic property of Gorensteinness. In this paper, we introduce a new combinatorial property, called *domino-stability*, and we prove that the switching rook polynomial of a collection of cells \mathcal{P} is palindromic if and only if \mathcal{P} is domino-stable. Building upon this result, we derive new insights into the characterization of Gorenstein K -algebras arising from collections of cells.

INTRODUCTION

Chess is one of the most famous board games in the world, and throughout its history it has inspired a wide variety of combinatorial problems. One of the most classical examples, known as the *rook problem*, involves rooks, i.e., the chess pieces that can attack only horizontally or vertically. This problem consists in determining the *rook polynomial*, that is, the generating function whose k -th coefficient is the number of ways to place k rooks on a pruned chessboard with at most one rook per row and column. The rook polynomial of a skew diagram is intimately connected with the enumeration of permutations with specific properties, a relation first explored in [13] and further developed in [23]. For a comprehensive treatment of permutations with forbidden positions, we refer the reader to [26, Chapter 2].

Over the years, rook polynomials have gained prominence due to their applications in various areas (see [7, 8] and the references therein), and several variants have been proposed, as in [5]. One of the most relevant in combinatorial commutative algebra is the *switching rook polynomial*. To provide a working formulation of it, let us consider a collection of cells \mathcal{P} , viewed as a pruned chessboard. We say that one or more rooks are *non-attacking* on \mathcal{P} whenever no horizontal or vertical path of edge-adjacent cells in \mathcal{P} connects two of them. Furthermore, if F_1 and F_2 are two placements of k non-attacking rooks on \mathcal{P} , we identify F_1 and F_2 whenever F_2 can be obtained from F_1 through a finite sequence of switchings, i.e., by moving pairs of rooks occupying opposite corners of a rectangle entirely contained in \mathcal{P} , from the diagonal to the anti-diagonal or vice versa. Then, the *switching rook polynomial* of \mathcal{P} is defined as

$$\tilde{r}_{\mathcal{P}}(t) = \sum_{k=0}^{r(\mathcal{P})} \tilde{r}_k(\mathcal{P}) t^k,$$

where $r(\mathcal{P})$ denotes the *rook number* of \mathcal{P} , i.e., the maximum number of non-attacking rooks that may be placed on \mathcal{P} , and $\tilde{r}_k(\mathcal{P})$ is the number of equivalence classes of configurations of k non-attacking rooks on \mathcal{P} under switching operations, for $0 \leq k \leq r(\mathcal{P})$.

Key words and phrases. Collection of cells, rook polynomial, palindromicity, Gorenstein.

The significance of the switching rook polynomial arises in combinatorial commutative algebra from its connection with the Hilbert–Poincaré series of the K -algebras associated with collections of cells. Starting from a collection of cells \mathcal{P} , one may construct the binomial ideal $I_{\mathcal{P}}$ generated by the inner 2-minors of \mathcal{P} in the polynomial ring $S_{\mathcal{P}} = K[x_v : v \text{ is a vertex of } \mathcal{P}]$, where K is a field. The K -algebra $K[\mathcal{P}] := S_{\mathcal{P}}/I_{\mathcal{P}}$ is called the coordinate ring of \mathcal{P} . This construction was introduced in [19] as a generalization of the well-known theory of 2-minor determinantal ideals of an $m \times n$ matrix of indeterminates. Refer to [2] for more details on determinantal ideals. The main focus of this research line is the study of the algebraic invariants of $K[\mathcal{P}]$ via the combinatorial geometry of \mathcal{P} . Since its introduction, this topic has been extensively investigated, leading to almost forty related publications, which the reader may consult in the recent survey [17].

What grants the switching rook polynomial its central relevance in the study of ideals of inner 2-minors of a collection of cells \mathcal{P} is its matching with the h -polynomial of $K[\mathcal{P}]$. A first connection was studied for polyominoes, that is, planar figures formed by joining unit squares edge to edge; for a comprehensive overview of polyominoes, see [6]. It was initially observed in [4] that the Castelnuovo–Mumford regularity of $K[\mathcal{P}]$ coincides with the rook number of \mathcal{P} , when \mathcal{P} is an L -convex polyomino. Later, it was shown in [22] that the h -polynomial of $K[\mathcal{P}]$ coincides with the switching rook polynomial of \mathcal{P} , if \mathcal{P} is a free-hole polyomino containing no square tetromino. An analogous result was obtained in [10, 14, 20] for polyominoes with at most one hole and possibly containing square tetrominoes. A further step forward was recently made in [18], where this equality between the h -polynomial and the switching rook polynomial was proven for convex collections of cells with quadratic Gröbner bases. In the same work, the authors also provided an algorithm for computing the switching rook polynomial and, on the basis of extensive computations, conjectured that this equality holds for arbitrary collections of cells ([18, Conjecture 2.4]). In this setting, the foundational work of Stanley [24] provides a nice and strong inspiration for analyzing the palindromicity of the switching rook polynomial, as it relates the palindromicity of the h -polynomial of a standard graded K -algebra to its Gorenstein property. Recall that a polynomial $p(t) = p_0 + \dots + p_d t^d$ in $\mathbb{Z}_{>0}[t]$ is said to be *palindromic* if $p_i = p_{d-i}$ for all $i = 0, \dots, \lfloor d/2 \rfloor$. It is worth mentioning that palindromic polynomials are studied not only in algebraic combinatorics for their elegant symmetries, but also in fields such as analysis and cryptography for their applications (see [12]); however, no analogous applications have been observed for the switching rook polynomial to date.

In this work, we geometrically characterize all collections of cells with palindromic switching rook polynomial. For this purpose, we introduce a novel combinatorial and geometric property, termed *domino-stability* (see Definition 2.4), and show that, if \mathcal{P} is a collection of cells, then its switching rook polynomial $\tilde{r}_{\mathcal{P}}(t)$ is palindromic if and only if \mathcal{P} is domino-stable (see Theorem 5.1).

The paper is organized as follows. Section 1 serves as a preliminary section and is divided into two subsections for clarity. In Subsection 1.1 we provide all relevant definitions and known properties of collections of cells, and in Subsection 1.2 we formally define the switching rook polynomial and discuss its properties.

In Section 2 we introduce and investigate the notion of *domino-stability* for a collection of cells (see Definition 2.4). We first show that every domino-stable collection of cells contains at least one stable square (see Proposition 2.6 and Definition 2.7). We then examine the switching rook polynomial of a square polyomino, providing an explicit bijection that explains its palindromicity (see Discussion 2.8), and conclude with Proposition 2.9, showing that certain cells of a domino-stable collection of cells are aligned horizontally and vertically with some stable squares.

Section 3 is devoted to establishing that domino-stability constitutes a sufficient condition for the palindromicity of the switching rook polynomial. The section begins with Lemma 3.1, a preliminary yet fundamental result, which shows that for a domino-stable collection of cells \mathcal{P} there exists, up to switches, a unique placement of $r(\mathcal{P})$ non-attacking rooks on \mathcal{P} , obtained by placing

all rooks exclusively on the stable squares of \mathcal{P} . This key result, together with Discussion 2.8 and Proposition 2.9, is then employed in Proposition 3.2, in order to explicitly construct a bijection between the equivalence classes of configurations of k non-attacking rooks and those of $r(\mathcal{P}) - k$ rooks. As a consequence, the switching rook polynomial of \mathcal{P} is shown to be palindromic.

In Section 4, we establish that domino-stability is a necessary condition for the palindromicity of the switching rook polynomial (see Proposition 4.3). The core of the argument lies in Proposition 4.2, where we show that if a collection of cells \mathcal{P} is not domino-stable and admits, up to switches, a unique configuration of $r(\mathcal{P})$ non-attacking rooks on \mathcal{P} (equivalently, $\tilde{r}_d(\mathcal{P}) = 1$ with $d = r(\mathcal{P})$), then necessarily $\tilde{r}_{d-1}(\mathcal{P}) > \tilde{r}_1(\mathcal{P})$. In other words, the number of equivalence classes of $(r(\mathcal{P}) - 1)$ non-attacking rooks on \mathcal{P} strictly exceeds the number of cells of \mathcal{P} .

Finally, in Section 5, we present the main result of this paper, stated below.

Theorem 0.1. (*Theorem 5.1*) *Let \mathcal{P} be a collection of cells and $\tilde{r}_{\mathcal{P}}(t)$ be the switching rook polynomial of \mathcal{P} . Then, $\tilde{r}_{\mathcal{P}}(t)$ is palindromic if and only if \mathcal{P} is domino-stable.*

Notably, the above theorem largely recovers [1, Corollary 5.16], which describes the palindromicity of the switching rook polynomial (referred to there as the nested rook polynomial) for skew diagrams. Furthermore, we present an interesting and unexpected development arising from the above result, that is, a potential characterization of the Gorenstein coordinate rings of collections of cells. Assuming that [18, Conjecture 2.4] holds and in light of Stanley's results [24], we have the following immediate corollary.

Corollary 0.2. (*Corollary 5.3*) *Let \mathcal{P} be a collection of cells satisfying [18, Conjecture 2.4], i.e., such that the h -polynomial of $K[\mathcal{P}]$ coincides with the switching rook polynomial of \mathcal{P} .*

- (1) *If $K[\mathcal{P}]$ is Gorenstein, then \mathcal{P} is domino-stable;*
- (2) *Suppose that $K[\mathcal{P}]$ is a Cohen-Macaulay domain, then the converse of (1) is true: that is, if \mathcal{P} is domino-stable, then $K[\mathcal{P}]$ is Gorenstein.*

This naturally motivates the search for supplementary geometric conditions on the structure of collections of cells to be imposed alongside domino-stability, in order to obtain a sufficient criterion for the Gorenstein property, in the non-domain case. The evidence presented below provides substantial support for the belief that domino-stability may, surprisingly, be sufficient to characterize Gorensteinness.

Proposition 0.3. (*Proposition 5.5*) *Let \mathcal{P} be a domino-stable collection of cells with rank less than or equal to 10 or a domino-stable polyomino with rank less than or equal to 12. Then $K[\mathcal{P}]$ is Gorenstein.*

The proof of the above result is purely computational and is based on the framework developed in [16]. This evidence naturally suggests the following conjecture:

Conjecture 0.4. (*Conjecture 5.6*) *Let \mathcal{P} be a collection of cells. Then, the following are equivalent:*

- (1) *$K[\mathcal{P}]$ is Gorenstein;*
- (2) *the h -polynomial of $K[\mathcal{P}]$ is palindromic;*
- (3) *the switching rook polynomial of \mathcal{P} is palindromic;*
- (4) *\mathcal{P} is domino-stable.*

This phenomenon is rather surprising. As noted by Stanley in [24, Example 4.5], even for relatively simple monomial ideals, weakening the primality assumption shows that palindromicity does not guarantee the Gorenstein property: for example, $K[x, y, z, w]/(xw, yw, xyz)$ is a reduced Cohen-Macaulay K -algebra with a palindromic h -polynomial, yet it is not Gorenstein. In contrast, for ideals of inner 2-minors of collections of cells, palindromicity alone appears sufficient to ensure the Gorenstein property.

1. COLLECTIONS OF CELLS AND SWITCHING ROOK POLYNOMIALS

In this section, we present the combinatorial preliminaries on collections of cells and provide the definition and basic properties of the switching rook polynomial.

1.1. Collection of cells. Let $(i, j), (k, l) \in \mathbb{Z}^2$. We define the partial order $(i, j) \leq (k, l)$ if and only if $i \leq k$ and $j \leq l$. Given $a = (i, j)$ and $b = (k, l)$ in \mathbb{Z}^2 with $a \leq b$, the set $[a, b] = \{(m, n) \in \mathbb{Z}^2 : i \leq m \leq k, j \leq n \leq l\}$ is called an *interval* of \mathbb{Z}^2 . If $i < k$ and $j < l$, the interval $[a, b]$ is said to be *proper*, in which case we refer to a and b as diagonal corners of $[a, b]$, and to $c = (i, l)$ and $d = (k, j)$ as the anti-diagonal corners. If $j = l$ (or $i = k$) then a and b are in a *horizontal* (or *vertical*) *position*. We denote by $]a, b[$ the set $\{(m, n) \in \mathbb{Z}^2 : i < m < k, j < n < l\}$. A proper interval $C = [a, b]$ where $b = a + (1, 1)$ is called a *cell* of \mathbb{Z}^2 . The points a, b, c , and d are respectively referred to as the *lower left*, *upper right*, *upper left* and *lower right corners* of C . We denote the set of *vertices* and *edges* of C by $V(C) = \{a, b, c, d\}$ and $E(C) = \{\{a, c\}, \{c, b\}, \{b, d\}, \{d, a\}\}$, respectively.

Let \mathcal{P} be a non-empty collection of cells in \mathbb{Z}^2 . We define the vertex and edge sets as $V(\mathcal{P}) = \bigcup_{C \in \mathcal{P}} V(C)$ and $E(\mathcal{P}) = \bigcup_{C \in \mathcal{P}} E(C)$, respectively. The *rank* of \mathcal{P} , denoted by $|\mathcal{P}|$, is the number of cells in \mathcal{P} . We say that \mathcal{P} is a *polyomino* if for any two distinct cells C and D in \mathcal{P} there exists a sequence of cells $\mathcal{C} : C = C_1, \dots, C_m = D$ of \mathcal{P} such that $C_i \cap C_{i+1}$ is an edge of C_i and C_{i+1} , for all $i = 1, \dots, m - 1$. Analogously, \mathcal{P} is *weakly connected* if for any two distinct cells in \mathcal{P} there exists such a sequence with $C_i \cap C_{i+1} \neq \emptyset$, for all $i = 1, \dots, m - 1$. A *connected component* \mathcal{P}' of \mathcal{P} is a polyomino contained in \mathcal{P} which is maximal with respect to the set inclusion, that is if $A \in \mathcal{P} \setminus \mathcal{P}'$ then $\mathcal{P}' \cup \{A\}$ is not a polyomino. For instance, in Figures 1 (A) and (B) we illustrate a polyomino and a weakly connected collection of cells with three connected components, respectively.

FIGURE 1. A polyomino, a weakly connected collection of cells and a bounding rectangle of a polyomino.

Consider two cells A and B of \mathbb{Z}^2 with $a = (i, j)$ and $b = (k, l)$ as the lower left corners of A and B , respectively, with $a \leq b$. The *cell interval* $[A, B]$, also called a *rectangle*, is the set of the cells of \mathbb{Z}^2 with lower left corner (r, s) such that $i \leq r \leq k$ and $j \leq s \leq l$. The *width* and the *height* of $[A, B]$, denoted by $w([A, B])$ and $h([A, B])$, represent the number of horizontal and vertical cells of $[A, B]$, respectively. Specifically, $w([A, B]) = k - i + 1$ and $h([A, B]) = l - j + 1$. The *size* of $[A, B]$ is defined by $h([A, B])w([A, B])$ and is denoted by $\text{size}([A, B])$. We say that $[A, B]$ is *horizontal* (respectively, *vertical*) if $h([A, B]) \geq w([A, B])$ (respectively, $h([A, B]) \leq w([A, B])$). If $h([A, B]) = w([A, B])$, then $[A, B]$ is said to be a *square*. Note that a square can be regarded simultaneously as both a vertical and a horizontal rectangle. If \mathcal{P} is a collection of cells, then we say that $[A, B]$ is the *minimal bounding rectangle* of \mathcal{P} if $\mathcal{P} \subseteq [A, B]$ and there does not exist any rectangle of \mathbb{Z}^2 containing \mathcal{P} that is properly contained in $[A, B]$ (Figure 1 (C)). A *maximal rectangle* of \mathcal{P} is a rectangle \mathcal{R} of cells of \mathcal{P} such that no other rectangle whose cells are all in \mathcal{P} properly contains \mathcal{R} . If (i, j) and (k, l) are in horizontal (or vertical) position, we say that the cells A and B are in a *horizontal* (or *vertical*) *position*. Consider two cells, A and B , of \mathcal{P} in a vertical (respectively, horizontal) position. The cell interval $[A, B]$ is called a *column* (respectively,

a *row*) of \mathcal{P} if the cells A and B are in vertical (respectively, horizontal) position, all the cells in $[A, B]$ belong to \mathcal{P} , and there is no cell interval $[A', B']$ with A' and B' in vertical (respectively, horizontal) position such that $[A, B] \subsetneq [A', B']$. The polyomino in Figure 1 (A) has eight maximal rectangles, nine columns and seven rows.

Since an interval in \mathbb{Z}^2 uniquely corresponds to a cell interval in \mathbb{Z}^2 , we associate an interval I of \mathbb{Z}^2 with its corresponding rectangle, denoted by $\mathcal{R}(I)$. If $I = [a, b]$ and c, d are the anti-diagonal corners of I , then the two cells of $\mathcal{R}(I)$ containing a or b (respectively, c or d) are called *diagonal* (respectively, *anti-diagonal*) *corner cells* of $\mathcal{R}(I)$. We say that an interval I is an *inner interval* of \mathcal{P} if $\mathcal{R}(I) \subseteq \mathcal{P}$.

1.2. Switching rook polynomial. We now introduce the terminology of non-attacking rooks on a collection of cells and the switching rook polynomial.

Let \mathcal{P} be a collection of cells. We say that two rooks R_1 and R_2 *coincide* or *overlap* if they are located in the same cell of \mathcal{P} . Two rooks R_1 and R_2 are in *attacking position* or *attacking rooks* in \mathcal{P} if they do not overlap and there exists a row or a column of \mathcal{P} that contains the cells where R_1 and R_2 are placed. In contrast, two rooks are in *non-attacking position* or *non-attacking rooks* in \mathcal{P} if they do not overlap and they are not in attacking position. A *j-rook configuration* in \mathcal{P} is a set of j rooks arranged in non-attacking positions within \mathcal{P} , where $j \geq 0$; for convention, the 0-rook configuration is \emptyset . We say that a *j-rook configuration* in \mathcal{P} is *maximal* if there does not exist any *k-rook configuration* in \mathcal{P} , with $k > j$, that properly contains it. The *rook number* $r(\mathcal{P})$ is the maximum number of rooks that can be placed in \mathcal{P} in non-attacking positions. In Figures 2 (A) and (B), we illustrate a maximal 5-rook configuration and an $r(\mathcal{P})$ -rook configuration in the same collection \mathcal{P} of cells, respectively, where $r(\mathcal{P}) = 7$.

We denote by $\mathcal{R}_j(\mathcal{P})$ the set of all *j-rook configurations* of \mathcal{P} for $j \in \{0, \dots, r(\mathcal{P})\}$, with the convention that $\mathcal{R}_0(\mathcal{P})$ represents the empty configuration (i.e., $|\mathcal{R}_0(\mathcal{P})| = 1$). Note that the collection $\bigcup_{j=0}^{r(\mathcal{P})} \mathcal{R}_j(\mathcal{P})$ forms a simplicial complex, known as the *rook complex* of \mathcal{P} . Two non-attacking rooks in \mathcal{P} are said to be in *switching position* if they are placed in the diagonal (respectively, anti-diagonal) corner cells of $\mathcal{R}(I)$, for some inner interval I of \mathcal{P} , and in such a case we say that the rooks are in a *diagonal* (respectively, *anti-diagonal*) position.

Fix $j \in \{0, \dots, r(\mathcal{P})\}$. Let $F \in \mathcal{R}_j(\mathcal{P})$. Consider two switching rooks, R_1 and R_2 , within F , positioned diagonally (or anti-diagonally) in $\mathcal{R}(I)$ for some inner interval I . Let R'_1 and R'_2 be the rooks in the anti-diagonal (or diagonal, respectively) cells of $\mathcal{R}(I)$. Then the set $(F \setminus \{R_1, R_2\}) \cup \{R'_1, R'_2\}$ also belongs to $\mathcal{R}_j(\mathcal{P})$. This operation of replacing R_1 and R_2 by R'_1 and R'_2 is called a *switch of R_1 and R_2* . This defines an equivalence relation \sim on $\mathcal{R}_j(\mathcal{P})$: $F_1 \sim F_2$ if F_2 can be obtained from F_1 through a sequence of switches. In this case, we say that F_1 and F_2 are *equivalent with respect to \sim* (or *same up to switches*). Figures 2 (C) and (D) show two 4-rook configurations that are equivalent with respect to \sim .

Let $\tilde{\mathcal{R}}_j(\mathcal{P}) = \mathcal{R}_j(\mathcal{P}) / \sim$ be the quotient set of equivalence classes. We define $\tilde{r}_j(\mathcal{P}) = |\tilde{\mathcal{R}}_j(\mathcal{P})|$ for $j \in \{0, \dots, r(\mathcal{P})\}$, with the convention that $\tilde{r}_0(\mathcal{P}) = 1$. The *switching rook polynomial* of \mathcal{P} is then defined as the polynomial in $\mathbb{Z}_{>0}[t]$:

$$\tilde{r}_{\mathcal{P}}(t) = \sum_{j=0}^{r(\mathcal{P})} \tilde{r}_j(\mathcal{P}) t^j.$$

For example, for the collection of cells in Figures 2 (C) or (D), $\tilde{r}_{\mathcal{P}}(t) = 1 + 8t + 19t^2 + 14t^3 + 3t^4$. In general, the switching rook polynomial of a collection of cells can be computed using the routine implemented in [15].

Definition 1.1. Let \mathcal{Q} be a rectangle with $w(\mathcal{Q}) = m$ and $h(\mathcal{Q}) = n$. After a suitable translation in the plane, we may assume that $\mathcal{Q} = \mathcal{R}([(1, 1), (m + 1, n + 1)])$. We denote by A_{ij} the cell of

FIGURE 2. Examples of some arrangements of non-attacking rooks.

\mathcal{Q} with lower left corner (i, j) , for all $i \in [m]$ and $j \in [n]$. For simplicity, we can identify a rook arrangement with the set of the cells of \mathcal{Q} where the rooks are placed. We say that a k -rook configuration $\mathfrak{R} = \{A_{i_1 j_1}, \dots, A_{i_k j_k}\}$ in \mathcal{Q} is *canonical* if then the indices satisfy $i_1 < \dots < i_k$ and $j_1 < \dots < j_k$.

Remark 1.2. Let \mathcal{Q} be a rectangle with notations as in Definition 1.1. Then, for every k -rook configuration \mathfrak{R} in \mathcal{Q} there exists a unique canonical k -rook configuration \mathfrak{C} in \mathcal{Q} such that $\mathfrak{C} \sim \mathfrak{R}$. Indeed, if $\mathfrak{R} = \{A_{i_1 j_1}, \dots, A_{i_k j_k}\}$ is a non canonical k -rook configuration in \mathcal{Q} , then we have two rooks of \mathfrak{R} , namely $A_{i_t j_t}$ and $A_{i_{t'} j_{t'}}$ for some $t, t' \in [k]$, that are in anti-diagonal position. Assume $i_t < i_{t'}$ and $j_t > j_{t'}$. Then one can replace $A_{i_t j_t}$ and $A_{i_{t'} j_{t'}}$ by $A_{i_t j_{t'}}$ and $A_{i_{t'} j_t}$ in \mathfrak{R} , respectively. Repeating the same process, if needed, one obtains the canonical form of \mathfrak{R} after finite number of steps.

The aim of next discussion is to suitably extend the previous definition to the context of a collection of cells. Specifically, for every k -rook configuration \mathfrak{R} in a collection \mathcal{P} of cells, we define a unique k -rook configuration \mathfrak{C} in \mathcal{P} such that $\mathfrak{C} \sim \mathfrak{R}$ and the arrangement of the rooks of \mathfrak{F} in the maximal rectangles of \mathcal{P} is canonical in according to Definition 1.1. This configuration \mathfrak{F} will serve as the representative of the class $[\mathfrak{R}]_{\sim}$.

Discussion 1.3. Let \mathcal{P} be a collection of cells and $\mathcal{M}(\mathcal{P}) = \{\mathcal{B}_1, \dots, \mathcal{B}_p\}$ be the set of maximal rectangles of \mathcal{P} . Let \mathfrak{R} be a k -rook configuration in \mathcal{P} . Let \mathfrak{R}_i be the set of rooks of \mathfrak{R} which are placed on the cells of \mathcal{B}_i and $r_i = |\mathfrak{R}_i|$, for $i \in [p]$. We perform a sequence of switches step by step over the maximal rectangles $\mathcal{B}_1, \dots, \mathcal{B}_p$ of \mathcal{P} , to transform \mathfrak{R} into a k -rook configuration in \mathcal{P} such that the r_i -rook configuration in \mathcal{B}_i is canonical, for all $i \in [p]$.

Let $1 \leq i \leq p$. Denote by $\mathfrak{R}(\mathcal{B}_i, \mathfrak{C}_{i-1})$ the set of rooks of \mathfrak{C}_i which are placed on the cells of \mathcal{B}_i (with $\mathfrak{C}_0 = \mathfrak{R}$). By Remark 1.2, there exists a unique canonical r_i -rook configuration in \mathcal{B}_i , denoted by $\mathfrak{C}(\mathcal{B}_i, \mathfrak{C}_{i-1})$, such that $\mathfrak{C}(\mathcal{B}_i, \mathfrak{C}_{i-1}) \sim \mathfrak{R}(\mathcal{B}_i, \mathfrak{C}_{i-1})$. We then define $\mathfrak{C}_i = (\mathfrak{R} \setminus \mathfrak{R}(\mathcal{B}_i, \mathfrak{C}_{i-1})) \cup \mathfrak{C}(\mathcal{B}_i, \mathfrak{C}_{i-1})$. At the final step, when we obtain \mathfrak{C}_p , we set $\mathfrak{F} = \mathfrak{C}_p$. It is straightforward that \mathfrak{F} is a k -rook configuration in \mathcal{P} with $\mathfrak{F} \sim \mathfrak{R}$. For each $i \in [p]$, let \mathfrak{F}_i be the set of rooks in \mathfrak{F} that are placed on the cells of \mathcal{B}_i , and let us show that \mathfrak{F}_i is canonical. Suppose, for contradiction, that there exists an index $j \in [p]$ such that \mathfrak{F}_j is not canonical. This means there are two rooks in \mathfrak{F}_j that are in anti-diagonal position. If \mathcal{B}_k for some $k > j$ contains both A_1 and A_2 , then the diagonal position of R_1 and R_2 is trivially preserved. If A_1 lies in \mathcal{B}_{j_1} and A_2 in \mathcal{B}_{j_2} with $j_1, j_2 > j$ and $j_1 \neq j_2$, then the diagonal position is also preserved. Indeed, let C_1 and C_2 (respectively, H_1 and H_2) be the maximal columns (respectively, rows) of \mathcal{P} that contain A_1 and A_2 , respectively. Define: $\bar{C}_1 = C_1 \setminus \mathcal{B}_j$, $\bar{C}_2 = C_2 \setminus \mathcal{B}_j$, $\bar{H}_1 = \{C \in H_1 : C \text{ is at West of } A_1\}$ and $\bar{H}_2 = \{C \in H_2 : C \text{ is at East of } A_2\}$. Then R_1 (respectively, R_2) can be moved to a cell in $\bar{C}_1 \cup \bar{H}_1$ (respectively, $\bar{C}_2 \cup \bar{H}_2$), so in the new configuration, R_1 and R_2 are either in diagonal position or no longer in switching position. Hence, two rooks in \mathfrak{F}_j cannot be in anti-diagonal position, which

yields a contradiction.

Hence, \mathfrak{F} is a k -rook configuration in \mathcal{P} such that $\mathfrak{F} \sim \mathfrak{R}$ and \mathfrak{F}_i is canonical, for every $i \in [p]$.

Definition 1.4. Let \mathcal{P} be a collection of cells, and let $\mathcal{M}(\mathcal{P}) = \{\mathcal{B}_1, \dots, \mathcal{B}_p\}$ denote the set of maximal rectangles in \mathcal{P} . Given a k -rook configuration \mathfrak{R} in \mathcal{P} , the configuration \mathfrak{F} defined in Discussion 1.3 is called the *canonical* k -rook configuration of \mathfrak{R} (with respect to $\mathcal{B}_1, \dots, \mathcal{B}_p$).

Remark 1.5. In general, it is important to note that, given a k -rook configuration \mathfrak{R} in \mathcal{P} , there does not necessarily exist a unique k -rook configuration \mathfrak{C} in \mathcal{P} such that $\mathfrak{C} \sim \mathfrak{R}$ and the arrangement of the rooks of \mathfrak{F} in the maximal rectangles of \mathcal{P} is canonical. In Figure 3 (A) we have a 3-rook configuration \mathfrak{R} , and in (B) and (C) two 3-rook configuration in \mathcal{P} , namely \mathfrak{F}_1 and \mathfrak{F}_2 , such that $\mathfrak{F}_1, \mathfrak{F}_2 \sim \mathfrak{R}$ and the arrangements of the rooks of both \mathfrak{F}_1 and \mathfrak{F}_2 in the maximal rectangles of \mathcal{P} is canonical. Uniqueness is achieved only after fixing an ordering of the maximal rectangles of \mathcal{P} . Indeed, different labeling may lead to different canonical k -rook configurations. If we fix the labeling $\mathcal{B}_1 = [A, B]$, $\mathcal{B}_2 = [C, D]$, $\mathcal{B}_3 = [A, D]$, and $\mathcal{B}_4 = [C, B]$, the corresponding canonical configuration of \mathfrak{R} is shown in Figure 3 (B). On the other hand, if we instead fix the labeling $\mathcal{B}_1 = [C, D]$, $\mathcal{B}_2 = [A, B]$, $\mathcal{B}_3 = [A, D]$, and $\mathcal{B}_4 = [C, B]$, then the canonical configuration becomes the one shown in (C).

FIGURE 3. Three 3-rook configurations in \mathcal{P} .

2. A COMBINATORIAL PROPERTY: DOMINO-STABILITY OF A COLLECTION OF CELLS

In this section, we introduce a new combinatorial property, called *domino-stability*, which is closely related to the geometric structure of a collection of cells (see Definition 2.4). This property plays a crucial role, as it characterizes precisely those collections of cells whose switching rook polynomial is palindromic.

We begin by introducing a new operation on axis-aligned rectangles, termed *gluing*, which consists of joining them along parallel edges to form a larger rectangle.

Definition 2.1 (Gluing of axis-aligned rectangles). Let $\{\mathcal{R}_{ij} : i \in [r], j \in [s]\}$ be a non-empty family of axis-aligned rectangles and let $\mathcal{B} = \bigcup \{\mathcal{R}_{ij} : i \in [r], j \in [s]\}$. We denote by $A_{ij}^{(m,n)}$ the (m,n) -th cell of \mathcal{R}_{ij} , indexed from left to right and from bottom to top (see Figure 4 (A)). For all $i \in [r]$ and $j \in [s]$, we define $\ell_i = l(\mathcal{R}_{i1})$ and $\omega_j = w(\mathcal{R}_{1j})$. Moreover, we set $\ell = \sum_{p=1}^r \ell_p$ and $\omega = \sum_{q=1}^s \omega_q$. Let \mathcal{R} be a rectangle with cell B_{uv} , where $1 \leq u \leq \ell$ and $1 \leq v \leq \omega$, indexed from left to right and from bottom to top. The rectangle \mathcal{R} is said to be the *gluing* of \mathcal{B} , and it is denoted by $G(\mathcal{B})$.

Furthermore, the (m,n) -th cell of \mathcal{R}_{ij} is mapped to B_{uv} , where $u = m + \sum_{p=1}^{i-1} \ell_p$ and $v = n + \sum_{q=1}^{j-1} \omega_q$, and conversely, B_{uv} maps to $A_{ij}^{(m,n)}$, where $m = u - \sum_{p=1}^{i-1} \ell_p$ and $n = v - \sum_{q=1}^{j-1} \omega_q$. In this case, we say that $A_{ij}^{(m,n)}$ (respectively, B_{uv}) *corresponds to* B_{uv} (respectively, $A_{ij}^{(m,n)}$), *under the gluing*, or that $A_{ij}^{(m,n)}$ and B_{uv} are *corresponding cells under gluing*.

FIGURE 4. A family of axis-aligned rectangles and its gluing.

A vertex $a \in V(\mathcal{P})$ is called an *interior vertex* of \mathcal{P} if a is a vertex of four distinct cells of \mathcal{P} , otherwise it is called a *boundary vertex* of \mathcal{P} .

Proposition 2.2. *Let \mathcal{P} be a collection of cells and $\mathcal{M}(\mathcal{P}) = \{\mathcal{B}_1, \dots, \mathcal{B}_p\}$ be the set of all maximal rectangles of \mathcal{P} . Set $\overline{\mathcal{B}}_i = \mathcal{B}_i \setminus \left(\bigcup_{j \in [p] \setminus \{i\}} \mathcal{B}_j \right)$, for $i \in [p]$ and assume that $\overline{\mathcal{B}}_i \neq \emptyset$. Then $\overline{\mathcal{B}}_i$ consists of a union of axis-aligned rectangles.*

Proof. Observe that if $\mathcal{B}_i \cap \mathcal{B}_k = \emptyset$ for all $k \in [p] \setminus \{i\}$, then $\overline{\mathcal{B}}_i = \mathcal{B}_i$, and the claim follows trivially. Otherwise, let j_1 be the smallest index in $[p] \setminus \{i\}$ such that $\mathcal{B}_i \cap \mathcal{B}_{j_1} \neq \emptyset$. We distinguish two cases, depending on whether $V(\mathcal{B}_{j_1})$ contains a corner of \mathcal{B}_i .

- (1) Suppose that a corner of \mathcal{B}_i belongs to $V(\mathcal{B}_{j_1})$. Note that at most one corner of \mathcal{B}_i can lie in the interior of $V(\mathcal{B}_{j_1})$, otherwise \mathcal{B}_i would not be maximal, and that the four corners of \mathcal{B}_i cannot belong to $V(\mathcal{B}_{j_1})$ at the same time, otherwise $\mathcal{B}_i \subset \mathcal{B}_{j_1}$ so against the maximality of \mathcal{B}_i . If one of the corners of \mathcal{B}_i lies in the interior of \mathcal{B}_{j_1} , then there exist two distinct maximal rectangles of \mathcal{P} , one horizontal and one vertical, say \mathcal{B}_{m_1} and \mathcal{B}_{n_1} (with $m_1, n_1 \in [p] \setminus ([j_1] \cup \{i\})$), containing $\mathcal{B}_i \cap \mathcal{B}_{j_1}$; in this case, $\mathcal{B}_i \setminus (\mathcal{B}_{j_1} \cup \mathcal{B}_{m_1} \cup \mathcal{B}_{n_1})$ consists of a single rectangle, which we denote by \mathfrak{R}_1 . If no corner of \mathcal{B}_i is in the interior of \mathcal{B}_{j_1} , then $\mathcal{B}_i \setminus \mathcal{B}_{j_1}$ still consists of a single rectangle, which we again denote by \mathfrak{R}_1 .
- (2) Suppose now that no corner of \mathcal{B}_i is in $V(\mathcal{B}_{j_1})$. Then $\mathcal{B}_i \setminus \mathcal{B}_{j_1}$ clearly consists of two axis-aligned rectangles, which we indicate by R_1 and R_2 and set $\mathfrak{R}_1 = R_1 \cup R_2$.

Now, if $\mathfrak{R}_1 \cap \mathcal{B}_k = \emptyset$ for all $k \in [p] \setminus ([j_1] \cup \{i\})$, then $\overline{\mathcal{B}}_i = \mathfrak{R}_1$. In this case, \mathfrak{R}_1 is either a single rectangle or a union of two axis-aligned rectangles, and the claim follows. Otherwise, let j_2 be the minimum index in $[p] \setminus ([j_1] \cup \{i\})$ such that $\mathfrak{R}_1 \cap \mathcal{B}_{j_2} \neq \emptyset$. If \mathfrak{R}_1 is a rectangle, then we can proceed exactly as before in (1) or (2), replacing \mathcal{B}_i with \mathfrak{R}_1 . This yields, in the end, a single rectangle, which we denote by \mathfrak{R}_2 . Now, suppose that \mathfrak{R}_1 consists of the two axis-aligned rectangles R_1 and R_2 . We have then to consider the possible situations depending on whether $V(\mathcal{B}_{j_2})$ contains a corner of R_1 or R_2 , or not.

- (A) Suppose that $V(\mathcal{B}_{j_2})$ contains at least one corner of R_1 or R_2 . Without loss of generality, we may assume that both R_1 and R_2 are horizontally axis-aligned. We denote the lower-left, upper-right, upper-left, and lower-right corners of R_h by a_h, b_h, c_h , and d_h , respectively, for $h \in 1, 2$. With this notation, $\{c_1, b_2\}$, $\{b_2, d_2\}$, $\{a_1, d_2\}$, and $\{a_1, c_1\}$ cannot lie in the interior of \mathcal{B}_{j_2} , and the set $\{a_1, c_1, d_2, b_2\}$ cannot be contained in $V(\mathcal{B}_{j_2})$, as this would contradict the maximality of \mathcal{B}_i . If at least one of the corners b_1, d_1, c_2, a_2 lies in the interior of \mathcal{B}_{j_2} then $\mathfrak{R}_1 \setminus \mathcal{B}_{j_2}$ is either a rectangle or two aligned-axis rectangles, denoted by \mathfrak{R}_2 . If one of the corners a_1, c_1, b_2, d_2 is in the interior of \mathcal{B}_{j_2} , then there exist two distinct maximal rectangles of \mathcal{P} , one horizontal and one vertical, say $\mathcal{B}_{m'}$ and $\mathcal{B}_{n'}$ (with

- $m', n' \in [p] \setminus ([j_2] \cup \{i\})$, containing $\mathcal{R} \cap \mathcal{B}_{j_2}$; in this case, $\mathfrak{R}_1 \setminus (\mathcal{B}_{j_2} \cup \mathcal{B}_{m'} \cup \mathcal{B}_{n'})$ consists of either a single rectangle or of two axis-aligned rectangles \mathfrak{R}_1 , which we still denote by \mathfrak{R}_2 .
- (B) Suppose now that $V(\mathcal{B}_j)$ contains no corner of R_1 and R_2 . Then $\mathfrak{R}_1 \setminus \mathcal{B}_{j_2}$ clearly consists of either three or four axis-aligned rectangles. We set $\mathfrak{R}_2 = \mathfrak{R}_1 \setminus \mathcal{B}_{j_2}$.

Now, if $\mathfrak{R}_2 \cap \mathcal{B}_k = \emptyset$ for all $k \in [p] \setminus ([h] \cup \{i\})$, then $\overline{\mathcal{B}}_i = \mathfrak{R}_2$ and either \mathfrak{R}_2 is a rectangle or consists of two, three or four axis-aligned rectangles, so the claim follows. In the opposite case, we consider the smallest index j_2 in $[p] \setminus ([j_2] \cup \{i\})$ such that $\mathfrak{R}_2 \cap \mathcal{B}_{j_2} = \emptyset$. We then repeat arguments similar to those used before. In conclusion, since $[p]$ is finite, by iterating this argument, we eventually find $s \in [p]$ such that $\mathfrak{R}_s \cap \mathcal{B}_k = \emptyset$ for all $k \in [p] \setminus \{i\}$, \mathfrak{R}_s is a union of axis-aligned rectangles, and $\overline{\mathcal{B}}_i = \mathfrak{R}_s$, which proves the claim. \square

Example 2.3. Consider the polyomino \mathcal{P} in Figure 5 (A). The maximal intervals of \mathcal{P} are: $\mathcal{B}_1 = \mathcal{R}([(2, 3), (10, 7)])$, $\mathcal{B}_2 = \mathcal{R}([(1, 4), (11, 5)])$, $\mathcal{B}_3 = \mathcal{R}([(4, 3), (6, 9)])$, $\mathcal{B}_4 = \mathcal{R}([(7, 1), (9, 7)])$, $\mathcal{B}_5 = \mathcal{R}([(7, 1), (8, 9)])$ and $\mathcal{B}_6 = \mathcal{R}([(7, 8), (9, 9)])$. Observe that $\overline{\mathcal{B}}_1$ consists of axis-aligned rectangles, which are $\{A_{11}^{(1,1)}, A_{11}^{(2,1)}\}$, $\{A_{21}^{(1,1)}\}$, $\{A_{31}^{(1,1)}\}$, $\{A_{12}^{(1,1)}, A_{12}^{(2,1)}, A_{12}^{(2,1)}, A_{12}^{(2,2)}\}$, $\{A_{22}^{(1,1)}, A_{22}^{(1,2)}\}$ and $\{A_{32}^{(1,1)}, A_{32}^{(1,2)}\}$. The gluing of $\overline{\mathcal{B}}_1$ is a rectangle, illustrated in Figure 5 (B).

FIGURE 5. A polyomino and a gluing of $\overline{\mathcal{B}}_1$.

Definition 2.4 (Domino-stable). Let \mathcal{P} be a collection of cells and let $\mathcal{M}(\mathcal{P}) = \{\mathcal{B}_1, \dots, \mathcal{B}_p\}$ be the set of all maximal intervals of \mathcal{P} . Let $\overline{\mathcal{B}}_i = \mathcal{B}_i \setminus \left(\bigcup_{j \in [p] \setminus \{i\}} \mathcal{B}_j \right)$, for all $i \in [p]$. We say that \mathcal{P} is *domino-stable* if, for all $i \in [p]$, one of the following conditions holds:

- (1) if $\overline{\mathcal{B}}_i \neq \emptyset$, then $G(\overline{\mathcal{B}}_i)$ is a square; or
- (2) if $\overline{\mathcal{B}}_i = \emptyset$, then for every cell C in \mathcal{B}_i there exist two unique distinct indices $j, k \in [p] \setminus \{i\}$ such that $\overline{\mathcal{B}}_j$ (respectively, $\overline{\mathcal{B}}_k$) contains a cell of \mathcal{P} in horizontal (respectively, vertical) position with C .

Remark 2.5. Note that in Definition 2.4, both $\overline{\mathcal{B}}_j$ and $\overline{\mathcal{B}}_k$ are non-empty. Consequently, according to condition (1), $G(\overline{\mathcal{B}}_j)$ and $G(\overline{\mathcal{B}}_k)$ are squares. In Figures 6 (A) and (B), we have two convex polyominoes which are domino-stable. In contrast, Figures 6 (C) and (D) show two polyominoes, \mathcal{P}_1 and \mathcal{P}_2 , which do not satisfy this property. The failure occurs because the cell C lies in a maximal rectangle \mathcal{B}_i for which $\overline{\mathcal{B}}_i = \emptyset$, and there is no vertically aligned cell with C that belongs to $\overline{\mathcal{B}}$ for any maximal rectangle of \mathcal{P}_1 or \mathcal{P}_2 .

FIGURE 6. Two domino-stable polyominoes on the left, two no domino-stable on the right.

Proposition 2.6. *Let \mathcal{P} be a collection of cells and let $\mathcal{M}(\mathcal{P}) = \{\mathcal{B}_1, \dots, \mathcal{B}_p\}$ be the set of all maximal rectangles of \mathcal{P} . Then there exists an index $i \in [p]$ such that $\overline{\mathcal{B}_i} \neq \emptyset$.*

Proof. Let us assume that \mathcal{P} is a polyomino. Let $\mathcal{R} = [R_1, R_4]$ be the minimal bounding rectangle of \mathcal{P} , and let R_2 and R_3 be the anti-diagonal cells of \mathcal{R} such that $[R_1, R_4]$ form a horizontal cell interval. Since \mathcal{R} is the minimal bounding rectangle of \mathcal{P} , we obtain that $\mathcal{P} \cap [R_1, R_4] \neq \emptyset$. Then, consider a maximal row $[A, B]$ of \mathcal{P} such that $[A, B] \subseteq [R_1, R_4]$. Due to the maximality of $[A, B]$, there is exactly one maximal rectangle of \mathcal{P} , say \mathcal{B}_i for some $i \in [p]$, such that $[A, B] \subseteq \mathcal{B}_i$. Due to the maximality of \mathcal{B}_i , there is a maximal vertical column in \mathcal{B}_i , denoted by $[C, D]$, such that the cell at North of D is not in \mathcal{P} . Moreover, the adjacent cells at East of A , West of B and South of C do not belong to \mathcal{P} . Then $C \notin \mathcal{B}_j$ for all $j \in [p] \setminus \{i\}$, that is, $C \in \overline{\mathcal{B}_i}$, so $\overline{\mathcal{B}_i} \neq \emptyset$. Finally, if \mathcal{P} is a collection of cells, it is enough to consider one connected component, which is a polyomino, and the claim follows from the preceding discussion. \square

Definition 2.7 (Stable-square). Let \mathcal{P} be a collection of cells. We set

$$\mathcal{S}(\mathcal{P}) = \{G(\overline{\mathcal{B}}) : \mathcal{B} \in \mathcal{M}(\mathcal{P}) \text{ and } \overline{\mathcal{B}} \neq \emptyset\},$$

which is non-empty by Proposition 2.6. If \mathcal{P} is domino-stable, then every element of $\mathcal{S}(\mathcal{P})$ is a square; in this case, we refer to the elements of $\mathcal{S}(\mathcal{P})$ as the *stable squares* of \mathcal{P} .

Stable squares will play a crucial role in the subsequent results, so we first review a fundamental property of the switching rook polynomial of a square.

Discussion 2.8. Let \mathcal{S} be a square of size n^2 , where $n \in \mathbb{Z}_{>0}$. The rook number of \mathcal{S} is n , so let $\tilde{r}_{\mathcal{S}}(t) = \sum_{k=0}^n \tilde{r}_k(\mathcal{S})t^k$ be the switching rook polynomial of \mathcal{S} . It is well known that $K[\mathcal{S}]$ is Gorenstein ([27, pp.451-452]) and that the h -polynomial of $K[\mathcal{S}]$ coincides with the switching rook polynomial of \mathcal{S} ([20]). Therefore, by [24, Theorem 4.1], we have that $\tilde{r}_{\mathcal{S}}(t)$ is palindromic, meaning that $\tilde{r}_k(\mathcal{S}) = \tilde{r}_{n-k}(\mathcal{S})$ for all $k \in \{0, \dots, n\}$. This symmetry implies the existence of a bijective correspondence between $\tilde{\mathcal{R}}_k(\mathcal{S})$ and $\tilde{\mathcal{R}}_{n-k}(\mathcal{S})$, so, in what follows, we explicitly construct such a bijection. We may assume that $\mathcal{S} = \mathcal{R}([(1, 1), (n+1, n+1)])$ and we denote by A_{ij} the cell of \mathcal{S} with lower left corner (i, j) , for all $i, j \in [n]$. Moreover, we refer to A_{ii} for $i \in [n]$ as a *diagonal cell* of \mathcal{S} . For a non-empty canonical k -rook configuration $\mathcal{A} = \{A_{i_1 j_1}, \dots, A_{i_k j_k}\}$, we set $[n] \setminus \{i_1 < \dots < i_k\} = \{i'_1 < \dots < i'_{n-k}\}$ and $[n] \setminus \{j_1 < \dots < j_k\} = \{j'_1 < \dots < j'_{n-k}\}$. Then, we define $\phi_k : \tilde{\mathcal{R}}_k(\mathcal{S}) \rightarrow \tilde{\mathcal{R}}_{n-k}(\mathcal{S})$ as:

$$\phi_k([\mathcal{A}]_{\sim}) = \begin{cases} [\{A_{ii} : i \in [n]\}]_{\sim} & \text{if } k = 0 \text{ and } \mathcal{A} = \emptyset, \\ [\{A_{i'_1 j'_1}, \dots, A_{i'_{n-k} j'_{n-k}}\}]_{\sim} & \text{if } 0 < k \leq r(\mathcal{S}) \text{ and } \mathcal{A} = \{A_{i_1 j_1}, \dots, A_{i_k j_k}\}. \end{cases}$$

It is an easy exercise to verify that this map is well-defined and bijective. In Figure 7, we illustrated that, if $\mathcal{A} = \{A_{12}, A_{64}, A_{76}\}$, then $\phi_3([\mathcal{A}]_{\sim}) = [\{A_{21}, A_{33}, A_{45}, A_{57}, A_{88}\}]_{\sim}$. We provide an intuitive

explanation of how the construction of $\phi_k([\mathcal{A}]_{\sim})$ proceeds, as this may help the reader grasp the underlying philosophy of the arguments throughout the remainder of the paper.

- (1) Given a k -rook configuration in \mathcal{S} , consider its canonical arrangement namely \mathcal{A} .
- (2) Remove the rows and columns of \mathcal{S} that contain a rook of \mathcal{A} and glue the remaining rows and columns of \mathcal{S} to obtain a square \mathcal{S}' of size $n - k$.
- (3) Place the rooks on the diagonal cells of \mathcal{S}' and map these rooks back into \mathcal{S} by placing them in the corresponding cells under the gluing.

FIGURE 7. Rooks of \mathcal{A} (white) and of the representative of $\phi_3([\mathcal{A}]_{\sim})$ (black).

We conclude this section with the following result, which will be used throughout the paper. It formulates condition (2) of domino-stability for the cells in $\mathcal{B}_i \setminus \overline{\mathcal{B}_i}$, when $\overline{\mathcal{B}_i}$ is non-empty.

Proposition 2.9. *Let \mathcal{P} be a domino-stable collection of cells. Let $\mathcal{M}(\mathcal{P}) = \{\mathcal{B}_1, \dots, \mathcal{B}_p\}$ be the set of all maximal rectangles of \mathcal{P} and $\overline{\mathcal{B}_i} = \mathcal{B}_i \setminus \left(\bigcup_{j \in [p] \setminus \{i\}} \mathcal{B}_j\right)$, for $i \in [p]$, with $\overline{\mathcal{B}_i} \neq \emptyset$. Then for every cell C of $\mathcal{B}_i \setminus \overline{\mathcal{B}_i}$ there exist two unique and distinct indices $j, k \in [p]$ such that $\overline{\mathcal{B}_j}$ (respectively, $\overline{\mathcal{B}_k}$) contains a cell of \mathcal{P} in horizontal (respectively, vertical) position with C .*

Proof. It is sufficient to prove the claim when \mathcal{P} is a polyomino. Then, suppose \mathcal{P} is a polyomino and consider $C \in \mathcal{B}_i \setminus \overline{\mathcal{B}_i}$. Let \mathcal{H} be the maximal row of \mathcal{P} containing C , and let \mathcal{B}_j be the maximal rectangle in $\mathcal{M}(\mathcal{P})$ containing \mathcal{H} . We claim $\overline{\mathcal{B}_j} \neq \emptyset$. Suppose, for contradiction, that $\overline{\mathcal{B}_j} = \emptyset$. Then, by condition (2) of Definition 2.4, there exists a unique index $h \in [p] \setminus \{i\}$ such that $\overline{\mathcal{B}_h}$ contains a cell of \mathcal{H} ; let us denote this cell by D . Since $\overline{\mathcal{B}_h} = \mathcal{B}_h \setminus \left(\bigcup_{\alpha \in [p] \setminus \{h\}} \mathcal{B}_\alpha\right)$, it follows that D cannot be in \mathcal{B}_j , contradicting the fact that $D \in \mathcal{H} \subseteq \mathcal{B}_j$. Hence, $\overline{\mathcal{B}_j} \neq \emptyset$. We now show that there exists a cell of \mathcal{H} which belongs to $\overline{\mathcal{B}_j}$. Since $\overline{\mathcal{B}_j} \neq \emptyset$, we may consider a cell in $\overline{\mathcal{B}_j}$, that we denote by E . If $E \in \mathcal{H}$, then we are done. If $E \notin \mathcal{H}$, then consider the column of \mathcal{P} which contains E , that we indicate by \mathcal{C} . We denote by A the unique cell in $\mathcal{H} \cap \mathcal{C}$ and we claim that $A \in \overline{\mathcal{B}_j}$. In fact, \mathcal{C} is not contained in \mathcal{B}_ℓ , for all $\ell \neq i$, otherwise E would not belong to $\overline{\mathcal{B}_j}$; the conclusion same holds for \mathcal{H} . Therefore $A \in \overline{\mathcal{B}_j}$. To prove the uniqueness of the index j , suppose, for the sake of contradiction, that there exists an index $j' \in [p] \setminus \{i, j\}$ such that $\overline{\mathcal{B}_{j'}}$ contains a cell A' of \mathcal{P} in horizontal position with C , so $A' \in \mathcal{H}$. Since $\mathcal{H} \subseteq \mathcal{B}_j$ and $\overline{\mathcal{B}_{j'}} = \mathcal{B}_{j'} \setminus \left(\bigcup_{\beta \in [p] \setminus \{j'\}} \mathcal{B}_\beta\right)$, then A' cannot be in $\overline{\mathcal{B}_{j'}}$, which is a contradiction. The existence and uniqueness of the index $k \in [p]$ such that $\overline{\mathcal{B}_k}$ contains a cell of \mathcal{P} in vertical position with C can be proven by applying similar arguments as before. This completes the proof of the proposition. \square

3. DOMINO-STABILITY AS A SUFFICIENT CONDITION FOR THE PALINDROMICITY OF THE SWITCHING ROOK POLYNOMIAL

The aim of this section is to prove that domino-stability provides a sufficient condition for the switching rook polynomial to be palindromic. Before establishing this result, we present a preliminary lemma that describes the arrangement of a maximum number of non-attacking rooks in a domino-stable collection of cells, as well as its uniqueness up to switching operations.

Lemma 3.1. *Let \mathcal{P} be a domino-stable collection of cells. Let $\mathcal{M}(\mathcal{P}) = \{\mathcal{B}_1, \dots, \mathcal{B}_p\}$ and $\mathcal{S}(\mathcal{P}) = \{\mathcal{S}_1, \dots, \mathcal{S}_q\}$ be the sets of maximal rectangles and single squares of \mathcal{P} , respectively, where $q \leq p$. Then there exists a unique $r(\mathcal{P})$ -rook configuration of \mathcal{P} , up to switches, and*

$$r(\mathcal{P}) = \sum_{i=1}^q \sqrt{\text{size}(\mathcal{S}_i)}.$$

Proof. After suitable labeling of the maximal rectangles of \mathcal{P} , we may assume that $\overline{\mathcal{B}_i} \neq \emptyset$, for all $1 \leq i \leq q$. Moreover, we set $\mathcal{S}_i = G(\overline{\mathcal{B}_i})$ and $d_i = \sqrt{\text{size}(\mathcal{S}_i)}$, for each $i \in [q]$. Let \mathcal{T}_i denote the arrangement of d_i rooks, placed on the cells of $\overline{\mathcal{B}_i}$, which correspond under the gluing to the diagonal cells of \mathcal{S}_i , for all $i \in [q]$ (see Discussion 2.8). Finally, define $\mathcal{T} = \mathcal{T}_1 \sqcup \dots \sqcup \mathcal{T}_q$ and set $d = \sum_{i=1}^q d_i = |\mathcal{T}|$. We now prove that \mathcal{T} provides the unique way to place the maximum number of non-attacking rooks on \mathcal{P} , up to switches.

1) We firstly show that \mathcal{T} is a d -rook configuration in \mathcal{P} . Let $i \in [q]$. Since each rook in \mathcal{T}_i is placed in a cell of $\overline{\mathcal{B}_i}$, and by definition $\overline{\mathcal{B}_i} = \mathcal{B}_i \setminus \bigcup_{j \neq i} \mathcal{B}_j$, it follows that all rooks in \mathcal{T}_i are in non-attacking positions with those in \mathcal{T}_j for all $j \neq i$. Moreover, by definition of \mathcal{T}_i , every rook in \mathcal{T}_i is in non-attacking position with a rook in \mathcal{T}_i . Hence, \mathcal{T} is a d -rook configuration in \mathcal{P} .

2) Next, we prove that \mathcal{T} is maximal. Suppose, by contradiction, that there exists a k -rook configuration \mathcal{T}' in \mathcal{P} with $k > d$ such that $\mathcal{T} \subset \mathcal{T}'$. It is not restrictive to assume that $k = d + 1$, that is, $\mathcal{T}' = \mathcal{T} \cup \{R\}$, where R is a rook not in \mathcal{T} . Let C_R be the cell of \mathcal{P} where R is placed and \mathcal{B}_i be a maximal rectangle of \mathcal{P} containing C_R , for some $i \in [p]$. Since \mathcal{P} is domino-stable, the following holds.

- If $C_R \in \overline{\mathcal{B}_i}$, then $\overline{\mathcal{B}_i} \neq \emptyset$, so $G(\overline{\mathcal{B}_i})$ is a square by (1) of Definition 2.4 and all the columns and rows of $\overline{\mathcal{B}_i}$ are occupied by a rook of \mathcal{T} . Consequently, R is in an attacking position with a rook in \mathcal{T} , a contradiction.
- If $\overline{\mathcal{B}_i} \neq \emptyset$ and $C_R \in \mathcal{B}_i \setminus \overline{\mathcal{B}_i}$, then by Proposition 2.9 there exist two cells A and B of \mathcal{P} in horizontal and vertical position with C_R , and only two distinct indices $j, k \in [p]$ such that $A \in \overline{\mathcal{B}_j}$ and $B \in \overline{\mathcal{B}_k}$. Hence R is necessarily in an attacking position with a rook of \mathcal{T} , which is a contradiction.
- On the other hand, if $\overline{\mathcal{B}_i} = \emptyset$, then a similar previous contradiction arises from (2) of Definition 2.4.

In each case, we get a contradiction; therefore, we can conclude that \mathcal{T} is maximal.

3) First, observe that if \mathcal{U} is a d -rook configuration in \mathcal{P} , with all rooks placed only on cells of $\bigcup_{i \in [q]} \overline{\mathcal{B}_i}$, then $\mathcal{U} \sim \mathcal{T}$ by Discussion 2.8. We now show that if \mathcal{U} is an arrangement of k non-attacking rooks, not all placed in cells of $\bigcup_{i \in [q]} \overline{\mathcal{B}_i}$, then $k < d$. To this end, we decompose \mathcal{U} into $q + 1$ disjoint subsets: for each $i \in [q]$, let \mathcal{U}_i consist of the rooks placed on the cells of $\overline{\mathcal{B}_i}$, and let \mathcal{Q} consist of those placed on the cells of \mathcal{P} that do not belong to $\bigcup_{i \in [q]} \overline{\mathcal{B}_i}$. For each $i \in [q]$, let $r_i = |\mathcal{U}_i|$, so that $0 \leq r_i \leq d_i$. Define $r = \sum_{i=1}^q r_i$, and note that $\sum_{i=1}^q (d_i - r_i) = d - r$. We now claim that $2|\mathcal{Q}| \leq d - r$. Each rook R in \mathcal{Q} is placed on a cell, denoted by C_R , of $\mathcal{B}_j \setminus \overline{\mathcal{B}_j}$, for some $j \in [p]$. By (2) of Definition 2.4 or Proposition 2.9, in correspondence of C_R , there exist two unique and distinct indices $j, k \in [q]$ such that $\overline{\mathcal{B}_j}$ (respectively, $\overline{\mathcal{B}_k}$) contains a cell of \mathcal{P} in

horizontal (respectively, vertical) position with C_R . For all $i \in [q]$, let $\overline{\mathcal{T}}_i$ the set of rooks of \mathcal{T}_i which are in attacking position with some rook of \mathcal{Q} . Then $|\overline{\mathcal{T}}_i| \leq d_i - r_i$. Observe that, for each rook T in $\overline{\mathcal{T}}_i$, T attacks a unique rook in \mathcal{Q} , which in turn is attacked by a unique rook in $\overline{\mathcal{T}}_j$, for some $j \neq i$. Then $2|\mathcal{Q}| = \sum_{i=1}^q |\overline{\mathcal{T}}_i| \leq d - r$. Hence, it follows that $2|\mathcal{Q}| \leq d - r$, in particular, $|\mathcal{Q}| \leq d - r - |\mathcal{Q}|$. Therefore, since $\mathcal{U} = (\bigsqcup_{i=1}^q \mathcal{U}_i) \sqcup \mathcal{Q}$ and from the inequality $|\mathcal{Q}| \leq d - r - |\mathcal{Q}|$, we obtain $k = r + |\mathcal{Q}| \leq d - r - |\mathcal{Q}| + r = d - |\mathcal{Q}| < d$.

In conclusion, \mathcal{T} yields the unique $r(\mathcal{P})$ -rook configuration of \mathcal{P} , up to switches, thus completing the proof of our claim, since $r(\mathcal{P}) = |\mathcal{T}| = \sum_{i=1}^q \sqrt{\text{size}(\mathcal{S}_i)}$. \square

We are now ready to prove that the switching rook polynomial of a domino-stable collection of cells is always palindromic. The key idea is that, starting from the $r(\mathcal{P})$ -rook configuration described in the Lemma 3.1, any configuration of k rooks can be transformed, up to switches, into a configuration of $(r(\mathcal{P}) - k)$ non-attacking rooks, and vice versa.

Proposition 3.2. *Let \mathcal{P} be a collection of cells and $\tilde{r}_{\mathcal{P}}(t) = \sum_{j=0}^d \tilde{r}_j(\mathcal{P})$ be the switching rook polynomial of \mathcal{P} , where $d = r(\mathcal{P})$. If \mathcal{P} is domino-stable then $\tilde{r}_{\mathcal{P}}(t)$ is palindromic.*

Proof. To show that $\tilde{r}_{\mathcal{P}}(t)$ is palindromic, that is, $\tilde{r}_j(\mathcal{P}) = \tilde{r}_{d-j}(\mathcal{P})$ for all $j \in \{0, \dots, d\}$, we define a bijection $\rho_k : \tilde{\mathcal{R}}_k(\mathcal{P}) \rightarrow \tilde{\mathcal{R}}_{d-k}(\mathcal{P})$, for all $k \in 0, \dots, d$. Let us start by defining $\mathcal{M}(\mathcal{P}) = \{\mathcal{B}_1, \dots, \mathcal{B}_p\}$ and $\mathcal{S}(\mathcal{P}) = \{\mathcal{S}_1, \dots, \mathcal{S}_q\}$ as the sets of maximal rectangles and stable squares of \mathcal{P} , respectively, where $q \leq p$ and $\overline{\mathcal{B}}_i \neq \emptyset$ for all $i \in [q]$. Moreover, set $\mathcal{S}_i = G(\overline{\mathcal{B}}_i)$ and $d_i = \sqrt{\text{size}(\mathcal{S}_i)}$, for all $i \in [q]$. According to Lemma 3.1, there exists a unique $r(\mathcal{P})$ -rook configuration \mathcal{T} in \mathcal{P} , up to switches. Such a rook configuration is described in the first paragraph of the proof of Lemma 3.1, in particular, $\mathcal{T} = \mathcal{T}_1 \sqcup \dots \sqcup \mathcal{T}_q$ where \mathcal{T}_i denotes the arrangement of d_i rooks, placed on the cells of $\overline{\mathcal{B}}_i$, which correspond under the gluing to the diagonal cells of \mathcal{S}_i , for all $i \in [q]$. Moreover, we also have $d = \sum_{i=1}^q d_i = |\mathcal{T}|$.

Let now $k \in \{1, \dots, d-1\}$ and $[\mathfrak{R}]_{\sim} \in \tilde{\mathcal{R}}_k(\mathcal{P})$. Then we assume that \mathfrak{R} is a canonical k -rook configuration in \mathcal{P} (with respect to $\mathcal{B}_1, \dots, \mathcal{B}_p$). To define $\rho_k([\mathfrak{R}]_{\sim})$, we distinguish the following cases based on the placement of the rooks of \mathfrak{R} in \mathcal{P} .

Case 1) We suppose that the rooks of \mathfrak{R} are placed exclusively on cells belonging to the stable squares of \mathcal{P} (For an example, see Figure 8 (A)).

FIGURE 8. Case 1)

For all $i \in [q]$, let \mathfrak{R}_i denote the set of rooks of \mathfrak{R} which are placed on $\overline{\mathcal{B}}_i$ and $r_i = |\mathfrak{R}_i|$, so $0 \leq r_i \leq d_i$. Observe that a rook in \mathfrak{R}_i either overlaps a rook of \mathcal{T}_i or is in attacking position with two rooks of \mathcal{T}_i (see Figure 8 (B), where \mathcal{T} is in black). Next, consider $\mathcal{S}_i = G(\overline{\mathcal{B}}_i)$. Let \mathfrak{S}_i be the r_i -rook configuration obtained by placing rooks on the cells of \mathcal{S}_i that correspond, under

the gluing, to the cells of $\overline{\mathcal{B}_i}$, where the rooks of \mathfrak{R}_i are placed. We then apply ϕ_{r_i} to $[\mathfrak{S}_i]_{\sim}$ as defined in Discussion 2.8, and denote by \mathfrak{S}'_i the representative of $\phi_{r_i}([\mathfrak{S}_i]_{\sim})$. We can now map back \mathfrak{S}'_i from \mathcal{S}_i to $\overline{\mathcal{B}_i}$, that is, define \mathfrak{R}'_i as the $(d_i - r_i)$ -rook configuration whose rooks are placed on the cells of $\overline{\mathcal{B}_i}$ which correspond, under the gluing, to the cells of \mathcal{S}_i , where the rooks of \mathfrak{S}'_i are placed. It is straightforward that $\sum_{i \in [q]} (d_i - r_i) = d - k$ and $\bigcup_{i \in [q]} \mathfrak{R}'_i \in \mathcal{R}_{d-k}(\mathcal{P})$. We thus define $\rho_k([\mathfrak{R}]_{\sim}) = [\mathfrak{R}']_{\sim}$, where $\mathfrak{R}' = \bigcup_{i \in [q]} \mathfrak{R}'_i$. See Figure 8 (C) for an example of \mathfrak{R}' .

Case 2) Suppose that the rooks of \mathfrak{R} are placed exclusively on cells belonging to $\mathcal{B}_i \setminus \overline{\mathcal{B}_i}$, for $i \in [p]$ (see Figure 9 (A)).

FIGURE 9. Case 2)

Let \mathfrak{R}_i denote the configuration of rooks located on a cell of $\mathcal{B}_i \setminus \overline{\mathcal{B}_i}$. Note that \mathfrak{R}_i may be empty if no rooks of \mathfrak{R} are positioned on $\mathcal{B}_i \setminus \overline{\mathcal{B}_i}$ for a given $i \in [p]$. Let $I = \{i \in [p] : |\mathfrak{R}_i| \neq 0\}$. Now, for all $i \in I$, regardless of whether $\overline{\mathcal{B}_i}$ is empty or non-empty, by condition (2) of Definition 2.4 or Proposition 2.9, each rook of \mathfrak{R}_i is in an attacking position with only two rooks of \mathcal{T} . Therefore, denote by $\text{Atk}_{\mathcal{T}}(\mathfrak{R}_i)$ be the set of rooks of \mathcal{T} that are in attacking position with those in \mathfrak{R}_i (see Figure 9 (B), where \mathcal{T} is in black). Set

$$\mathfrak{R}' = \mathfrak{R} \cup \left(\mathcal{T} \setminus \left(\bigcup_{i \in I} \text{Atk}_{\mathcal{T}}(\mathfrak{R}_i) \right) \right).$$

It is straightforward to verify $\mathfrak{R}' \in \mathcal{R}_{d-k}(\mathcal{P})$. We thus define $\rho_k([\mathfrak{R}]_{\sim}) = [\mathfrak{R}']_{\sim}$ (see Figure 9 (C)).

Case 3) Assume that the rooks of \mathfrak{R} are placed both on cells belonging to $\mathcal{B}_i \setminus \overline{\mathcal{B}_i}$, for $i \in [p]$, and on cells belonging to the stable squares of \mathcal{P} . Let us first introduce the following notation.

- For all $i \in [q]$, \mathfrak{R}_i denotes the set of rooks of \mathfrak{R} on the cells of $\overline{\mathcal{B}_i}$, $r_i = |\mathfrak{R}_i|$ and $I = \{i \in [q] : \mathfrak{R}_i \neq \emptyset\}$.
- $\text{Atk}_{\mathcal{T}_i}(\mathfrak{R}_i)$ represents the set of rooks of \mathcal{T}_i that are in attacking position or overlap with those in \mathfrak{R}_i , for all $i \in [q]$.
- \mathfrak{F}_i denotes the set of rooks of \mathfrak{R} which are located in the cells of $\mathcal{B}_i \setminus \overline{\mathcal{B}_i}$, for all $i \in [p]$, and $J = \{i \in [p] : \mathfrak{F}_i \neq \emptyset\}$.
- I_1 is the set of indices of $i \in I$ such that a rook of \mathcal{T}_i is in attacking position with a rook of \mathfrak{F}_j for some $j \in J$. For all $i \in I_1$ and $j \in J$, denote by $\text{Atk}_{\mathcal{T}_i}(\mathfrak{F}_j)$ the set of rooks of \mathcal{T}_i that are in attacking position with a rook of \mathfrak{F}_j . Moreover, for each $i \in I_1$, let $J(i) = \{j \in J : \text{Atk}_{\mathcal{T}_i}(\mathfrak{F}_j) \neq \emptyset\}$.
- $I_2 := [q] \setminus I_1$ represents the set of indices of $i \in I$ such that no rook of \mathcal{T}_i is in attacking position with a rook of \mathfrak{F}_j , for all $j \in J$.

Here, we need to distinguish two sub-cases depending on whether $\text{Atk}_{\mathcal{T}_i}(\mathfrak{R}_i) \cap \text{Atk}_{\mathcal{T}_i}(\mathfrak{F}_j)$ is empty or not. Specifically, this distinction determines whether the switching of a rook in \mathfrak{R}_i and a rook in \mathfrak{F}_j , where $i \in I$ and $j \in J(i)$, causes one of the two to coincide with a rook in \mathcal{T}_i .

- (1) Suppose that $\text{Atk}_{\mathcal{T}_i}(\mathfrak{R}_i) \cap \text{Atk}_{\mathcal{T}_i}(\mathfrak{F}_j) = \emptyset$, for all $i \in I_1$ and $j \in J(i)$ (see Figures 10 (A) and (B)).

FIGURE 10. Case 3)-(1)

For all $i \in I_1$ and $j \in J(i)$, consider the rooks of $\mathfrak{R}_i \cup \text{Atk}_{\mathcal{T}_i}(\mathfrak{F}_j)$ and proceed as in Case 1), obtaining a rook configuration denoted by \mathfrak{R}'_i , which contains $d_i - r_i - |\text{Atk}_{\mathcal{T}_i}(\mathfrak{F}_j)|$ rooks. For all $i \in I_2$, we consider \mathfrak{R}_i and we apply again the arguments as in Case 1), obtaining a $(d_i - r_i)$ -rook configuration, namely \mathfrak{R}''_i . We define

$$\mathfrak{R}' = \left(\bigcup_{i \in I_1} \mathfrak{R}'_i \right) \cup \left(\bigcup_{i \in I_2} \mathfrak{R}''_i \right) \cup \left(\bigcup_{j \in J} \mathfrak{F}_j \right).$$

Observe that $\sum_{i \in I_2} (d_i - r_i) + \sum_{i \in I_1} (d_i - r_i - |\text{Atk}_{\mathcal{T}_i}(\mathfrak{F}_j)|) + \sum_{j \in J} |\mathfrak{F}_j| = d - k$ and $\mathfrak{R}' \in \mathcal{R}_{d-k}(\mathcal{P})$. We thus define $\rho_k([\mathfrak{R}]_{\sim}) = [\mathfrak{R}']_{\sim}$ (see Figure 10 (C)).

- (2) Suppose that $\text{Atk}(\mathfrak{R}_i, \mathcal{T}_i) \cap \text{Atk}(\mathfrak{F}_j, \mathcal{T}_i) \neq \emptyset$, for some $i \in I_1$ and $j \in J(i)$ (see Figure 11 (A)).

For each (i, j) such that $\text{Atk}(\mathfrak{R}_i, \mathcal{T}_i) \cap \text{Atk}(\mathfrak{F}_j, \mathcal{T}_i) \neq \emptyset$, we can perform suitable switches between the rooks of \mathfrak{R}_i and the rooks of \mathfrak{F}_j . These operations leads one of the rooks of \mathfrak{R}_i or \mathfrak{F}_j to coincide with a rook in \mathcal{T}_i . After all the switching operations, we obtain two new arrangements of non-attacking rooks, namely \mathfrak{R}^*_i and \mathfrak{F}^*_j , such that $\text{Atk}_{\mathcal{T}_i}(\mathfrak{R}^*_i) \cap \text{Atk}_{\mathcal{T}_i}(\mathfrak{F}^*_j) = \emptyset$ (see Figures 11 (B), (C) and (D)). Define

$$\mathfrak{R}^* = \left(\bigcup_{i \in I_1} \mathfrak{R}^*_i \right) \cup \left(\bigcup_{i \in I_2} \mathfrak{R}_i \right) \cup \left(\bigcup_{j \in J} \mathfrak{F}^*_j \right).$$

Then, we define $\rho_k([\mathfrak{R}]_{\sim})$ as ρ_k , defined previously in Case 3)-(1), acting on $[\mathfrak{R}^*]_{\sim}$ (Figure 11 (E)).

It is now easy to verify that for each $k \in \{1, \dots, d-1\}$ we have $\rho_{d-k} \circ \rho_k = \text{id}_{\tilde{\mathcal{R}}_k(\mathcal{P})}$ and $\rho_k \circ \rho_{d-k} = \text{id}_{\tilde{\mathcal{R}}_{d-k}(\mathcal{P})}$. Therefore, ρ_k is bijective. In addition to Lemma 3.1, the latter means that $\tilde{r}_j(\mathcal{P}) = \tilde{r}_{d-j}(\mathcal{P})$ for all $j \in \{0, \dots, d\}$. In conclusion, $\tilde{r}_{\mathcal{P}}(t)$ is palindromic. \square

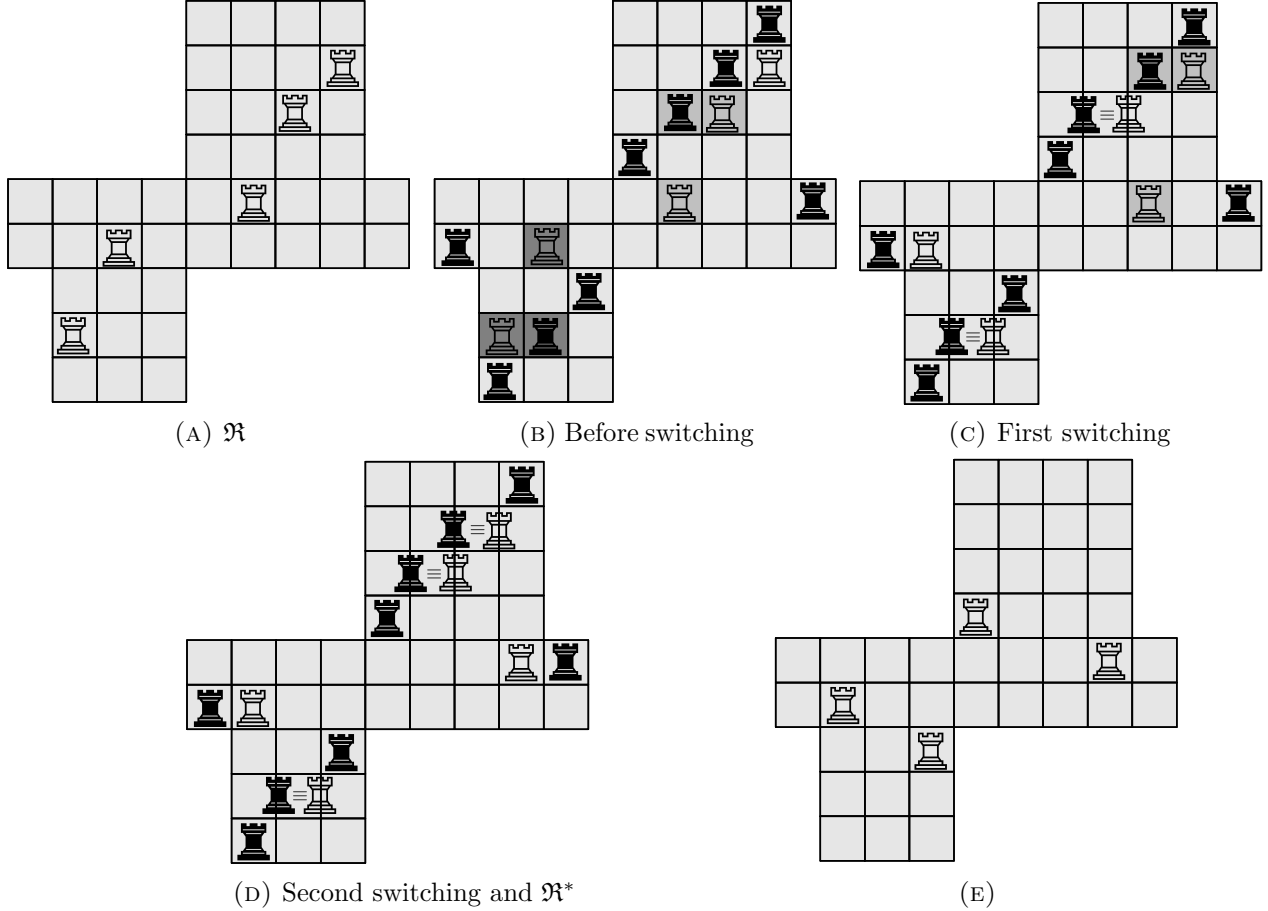

FIGURE 11. Case 3)-(2)

4. DOMINO-STABILITY AS A NECESSARY CONDITION FOR THE PALINDROMICITY OF THE SWITCHING ROOK POLYNOMIAL

Just as the previous section established a sufficient condition for the palindromicity, we now show that domino-stability is also a necessary condition for a switching rook polynomial to be palindromic. Before presenting the main result, we state a preliminary lemma.

Lemma 4.1. *Let \mathcal{P} be a collection of cells, $\mathcal{M}(\mathcal{P}) = \{\mathcal{B}_1, \dots, \mathcal{B}_p\}$ be the set of maximal rectangles of \mathcal{P} and $\tilde{r}_{\mathcal{P}}(t) = \sum_{j=0}^d \tilde{r}_j(\mathcal{P}) t^j$ be the switching rook polynomial of \mathcal{P} , where $d = r(\mathcal{P})$. Suppose that $\tilde{r}_d(\mathcal{P}) = 1$ and let \mathcal{T} be the unique canonical $r(\mathcal{P})$ -rook configuration in \mathcal{P} (with respect to $\mathcal{B}_1, \dots, \mathcal{B}_p$). Then:*

- (1) *every column of \mathcal{P} contains a cell occupied by a rook of \mathcal{T} , and the same holds for every row of \mathcal{P} ;*
- (2) *if R is a rook placed in a cell of \mathcal{P} , that does not contain any rook of \mathcal{T} , then there exist two unique rooks in \mathcal{T} that are in attacking position with R .*

Proof. (1) Assume by contradiction that C is a column of \mathcal{P} whose cells do not have any rook of \mathcal{T} . Now, if there were a row L of \mathcal{P} that intersects C and whose cells do not have any rook of \mathcal{T} , then we could consider $\mathcal{T} \cup \{F\}$, where F is a rook placed in the cell $C \cap L$; this would be a contradiction with the maximality of \mathcal{T} . Therefore, there must be a rook T in a cell of every row of \mathcal{P} that intersects C . Now, select a rook T' in a row L' , and consider $(\mathcal{T} \setminus \{T\}) \cup \{T'\}$, where T' is placed in the cell $C \cap L'$. This provides a $r(\mathcal{P})$ -rook configuration in \mathcal{P} that is not equivalent

to \mathcal{T} , contradicting the assumption $\tilde{r}_d(\mathcal{P}) = 1$. A similar argument shows that every row of \mathcal{P} contains a cell occupied by a rook of \mathcal{T} .

(2) Suppose that there are no two rooks of \mathcal{T} that are in attacking position with R . Indeed, if no rook of \mathcal{T} is in an attacking position with R , then $\mathcal{T} \cup \{R\}$ would be a set of non-attacking rooks, which contradicts the maximality of \mathcal{T} . Furthermore, suppose that there exists no rook of \mathcal{T} which is in the same row (respectively, column) of R , but R is in the same column (respectively, row) of a rook T of \mathcal{T} . In this case, replacing T with R yields a new configuration $\mathcal{T}' = (\mathcal{T} \setminus \{T\}) \sqcup \{R\} \in \mathcal{R}_d(\mathcal{P})$. Since \mathcal{T}' is obtained from \mathcal{T} by swapping a rook in the same column (respectively, row), then \mathcal{T} and \mathcal{T}' are not equivalent with respect to \sim , contradicting the assumption that $\tilde{r}_d(\mathcal{P}) = 1$. Finally, to prove uniqueness, it is enough to observe that we cannot have three rooks of \mathcal{T} in the attacking position with R , since this would imply that \mathcal{T} contains two attacking rooks, which contradicts the definition of \mathcal{T} . \square

Proposition 4.2. *Let \mathcal{P} be a collection of cells and $\tilde{r}_{\mathcal{P}}(t) = \sum_{j=0}^d \tilde{r}_j(\mathcal{P}) t^j$ be the switching rook polynomial of \mathcal{P} , where $d = r(\mathcal{P})$. Suppose that $\tilde{r}_d(\mathcal{P}) = 1$ and \mathcal{P} is not domino-stable. Then $\tilde{r}_1(\mathcal{P}) < \tilde{r}_{d-1}(\mathcal{P})$.*

Proof. Let $\mathcal{M}(\mathcal{P}) = \{\mathcal{B}_1, \dots, \mathcal{B}_p\}$ be the set of maximal rectangles of \mathcal{P} . Since $\tilde{r}_d(\mathcal{P}) = 1$, there exists a unique way to place $r(\mathcal{P})$ non-attacking rooks on \mathcal{P} , up to switches. Let $[\mathcal{T}]_{\sim} \in \tilde{\mathcal{R}}_d(\mathcal{P})$, where \mathcal{T} is the unique canonical $r(\mathcal{P})$ -rook configuration in \mathcal{P} (with respect to $\mathcal{B}_1, \dots, \mathcal{B}_p$). Note that $\tilde{r}_1(\mathcal{P}) = |\mathcal{P}|$. Let us begin by easily establishing an injection τ from $\tilde{\mathcal{R}}_1(\mathcal{P})$ to $\tilde{\mathcal{R}}_{d-1}(\mathcal{P})$. If R is a rook of \mathcal{T} , then $\mathcal{T} \setminus \{R\} \in \mathcal{R}_{d-1}(\mathcal{P})$. If $R \notin \mathcal{T}$, by Lemma 4.1 (2), there exists a unique pair of rooks of \mathcal{T} , namely $T_1^{(R)}$ and $T_2^{(R)}$, that are in attacking position with R . We now define the map $\tau : \tilde{\mathcal{R}}_1(\mathcal{P}) \rightarrow \tilde{\mathcal{R}}_{d-1}(\mathcal{P})$ by

$$\tau([\{R\}]_{\sim}) = \begin{cases} [\mathcal{T} \setminus \{R\}]_{\sim} & \text{if } R \in \mathcal{T}, \\ \left[\left(\mathcal{T} \setminus \{T_1^{(R)}, T_2^{(R)}\} \right) \sqcup \{R\} \right]_{\sim} & \text{if } R \notin \mathcal{T}. \end{cases}$$

for every $[R]_{\sim} \in \tilde{\mathcal{R}}_1(\mathcal{P})$. It is easy to verify that τ is well-defined and injective. Therefore, $\tilde{r}_1(\mathcal{P}) \leq \tilde{r}_{d-1}(\mathcal{P})$.

Now, we show that there exists $[\mathcal{R}]_{\sim} \in \tilde{\mathcal{R}}_{d-1}(\mathcal{P})$ such that $[\mathcal{R}]_{\sim} \notin \tau(\tilde{\mathcal{R}}_1(\mathcal{P}))$. The aim is to find three rooks R_1 , R_2 , and R_3 in \mathcal{T} such that the cells A and B , defined respectively as the intersection of the column of R_1 with the row of R_2 , and the intersection of the column of R_2 with the row of R_3 , do not belong simultaneously to the same inner interval of \mathcal{P} . In other words, two rooks placed in A and B are not in switching position, then, by removing R_1 , R_2 , and R_3 from \mathcal{T} and placing two new rooks in A and B , we obtain a $(d-1)$ -rook configuration whose equivalent class cannot come under τ from no class in $\tilde{\mathcal{R}}_1(\mathcal{P})$. We now distinguish two cases, which involve negating conditions (1) and (2) of Definition 2.4, respectively.

Case 1) Suppose that (1) of Definition 2.4 is false, that is, there exists $i \in [p]$ such that $\overline{\mathcal{B}_i} \neq \emptyset$ and $G(\overline{\mathcal{B}_i})$ is not a square. We may suppose that $G(\overline{\mathcal{B}_i})$ is a rectangle with width m and height n , where $m < n$. Moreover, for $j \in [m]$, we denote by H'_j and V'_j the bottom-most row and the leftmost column, respectively, of $G(\overline{\mathcal{B}_i}) \setminus (H'_{j-1} \cup V'_{j-1})$, where $H'_0 = V'_0 = \emptyset$; let us set $G_j = H'_j \cap V'_j$. We denote by C_j the cell of \mathcal{B}_i , corresponding to G_j under the gluing (see Figure 12 (A)) and by H_j and V_j be the column and the row of \mathcal{P} that contain C_j , respectively.

We briefly show that there exists a d -rook configuration \mathcal{T}' , equivalent to \mathcal{T} , such that a rook of \mathcal{T}' is placed in C_j , for every $j \in [m]$. Indeed, by Lemma 4.1 (1), there exists a rook of \mathcal{T} in a cell of H_j and another in a cell of V_j . If a rook is already placed in C_j , there is nothing to do. Otherwise, since $C_j \in \overline{\mathcal{B}_i}$, both H_j and V_j are entirely contained in \mathcal{B}_i , so we can switch the rooks in H_j and V_j . This yields a d -rook configuration equivalent to \mathcal{T} in which a rook is placed

FIGURE 12. Some illustrations for the proof of Case 1 of Proposition 4.3.

in C_j . Repeating this procedure for every $j \in [m]$, we obtain the desired claim. Therefore, it is not restrictive to assume that a rook of \mathcal{T} is placed in C_j for every $j \in [m]$. In particular, we denote by R_1 the rook of \mathcal{T} placed in C_1 .

From this point onward, we invite the reader to keep Figure 12 (A) in mind, as it may assist in following the argument. Let N be the cell at North of C_m . Since $G(\overline{B}_i)$ is a rectangle and $m < n$, the row of \mathcal{P} containing N is entirely contained in \mathcal{B}_i ; we denote this row by H_N . Furthermore, let A be the cell given by $V_1 \cap H_N$. By Lemma 4.1 (1), there exists a rook of \mathcal{T} placed in a cell of H_N ; we denote this cell by D and the corresponding rook by R_2 . Moreover, since for all $j \in [m]$ the cell C_j contains a rook of \mathcal{T} , it follows that D lies in $\mathcal{B}_i \setminus \overline{\mathcal{B}_i}$. Denote by V_D the column of \mathcal{P} , which contains D . Let B be the cell in $V_D \setminus \mathcal{B}_i$ having an edge in common with \mathcal{B}_i . We can easily see that at least one of the adjacent cells of B at West or at East belongs to \mathcal{P} ; indeed, if any of the adjacent cells of B at West or at East belongs to \mathcal{P} , then $\mathcal{T}' = (\mathcal{T} \setminus \{R_2\}) \cup \{R'\}$, where R' is a rook placed in B , is a d -rook configuration in \mathcal{P} not equivalent to \mathcal{T} , which is a contradiction with $\tilde{r}_d(\mathcal{P}) = 1$. Consider the row of \mathcal{P} that contains B , denoted by H_B . Then, by Lemma 4.1 (1), there exists a rook of \mathcal{T} in a cell of $H_B \setminus \{B\}$, which we denote by R_3 . Remind that R_1 and R_2 are on C_1 and D , respectively. Denote by R_A and R_B the rooks to be placed at A and B , respectively. Define $\mathcal{R} = (\mathcal{T} \setminus \{R_1, R_2, R_3\}) \cup \{R_A, R_B\}$. It is clear from the construction that $[\mathcal{R}]_{\sim} \in \tilde{\mathcal{R}}_{d-1}(\mathcal{P})$ and $[\mathcal{R}]_{\sim} \notin \tau(\tilde{\mathcal{R}}_1(\mathcal{P}))$, as required. Look at Figure 12 (B) for an example.

Case 2) Suppose, now, that (2) of Definition 2.4 is false. We may assume that there exists $i \in [p]$ such that $\overline{\mathcal{B}_i} = \emptyset$ and there is a cell C in \mathcal{B}_i for which there does not exist a unique index $j \in [p] \setminus \{i\}$ such that $\overline{\mathcal{B}_j}$ contains a cell in horizontal position with C . If there are two indices $j_1, j_2 \in [p] \setminus \{i\}$ such that $\overline{\mathcal{B}_{j_1}}$ and $\overline{\mathcal{B}_{j_2}}$ contain a cell, let us say C' , in horizontal with C , then $C' \in \overline{\mathcal{B}_{j_1}} = \mathcal{B}_{j_1} \setminus \left(\bigcup_{k \in [p] \setminus \{j_1\}} \mathcal{B}_k \right)$, so $C' \notin \mathcal{B}_{j_2}$, which contains $\overline{\mathcal{B}_{j_2}}$; therefore, $C' \notin \overline{\mathcal{B}_{j_2}}$, that is a contradiction. Hence, we have that $\overline{\mathcal{B}_j}$ does not have a cell in horizontal position with C , for all $j \in [p] \setminus \{i\}$. This guarantees that the row of \mathcal{P} that contains C , namely H_C , is entirely contained in \mathcal{B}_i . By Lemma 4.1 (1), there is a rook of \mathcal{T} in a cell of H_C ; we denote such a cell and rook by D and R_1 , respectively. We know that $\overline{\mathcal{B}_i} = \emptyset$; it is not restrictive to assume that \mathcal{B}_t and \mathcal{B}_u are maximal intervals of \mathcal{P} (with $u, t \in [p] \setminus \{i\}$), such that $\mathcal{B}_i \setminus (\mathcal{B}_t \cup \mathcal{B}_u) = \emptyset$, as in Figure 13 (A).

FIGURE 13. Some illustrations for the proof of Case 2 of Proposition 4.3.

Then D belongs to \mathcal{B}_u or \mathcal{B}_t . Observe that the cell X (respectively, Y) does not belong to \mathcal{B}_u (respectively, \mathcal{B}_t), otherwise \mathcal{B}_i would not be maximal. Let V_1 (respectively, V_2) be the left-most (respectively, right-most) column of \mathcal{B}_t (respectively, \mathcal{B}_u), $V_1 \cap H_C = \{A\}$ and $V_2 \cap H_N = \{A'\}$. Let V_D be the column of \mathcal{P} containing D . We need to distinguish two cases, depending on if $D \in \mathcal{B}_u$ or $D \in \mathcal{B}_t$. Assume $D \in \mathcal{B}_u$. Let B the cell in $V_D \setminus \mathcal{B}_i$ having an edge in common with \mathcal{B}_i , so $B \in \mathcal{P}$. Let now H_B be the row of \mathcal{P} containing B , so $|H_B| \geq 2$ and a rook R_2 of \mathcal{T} is in $H_B \setminus \{B\}$, otherwise $\tilde{r}_d(\mathcal{P}) \neq 1$. By Lemma 4.1 (1), there is a rook of \mathcal{T} also in $V_1 \setminus \{A\}$, that we call R_3 . Denote by R_A and R_B the rooks to be placed at A and B , respectively. Define $\mathcal{R} = (\mathcal{T} \setminus \{R_1, R_2, R_3\}) \cup \{R_A, R_B\}$. It is clear from the construction that $[\mathcal{R}]_\sim \in \tilde{\mathcal{R}}_{d-1}(\mathcal{P})$ and $[\mathcal{R}]_\sim \notin \tau(\tilde{\mathcal{R}}_1(\mathcal{P}))$, as required. See Figure 13 (B) for an example.

In the second case, that is, $D \in \mathcal{B}_t$, we can argue similarly as done before. Let B' be the cell in $V_D \setminus \mathcal{B}_i$ having an edge in common with \mathcal{B}_i , $H_{B'}$ be the row of \mathcal{P} containing B' and R_2 be a rook of \mathcal{T} in $H_{B'} \setminus \{B'\}$. We denote by R_3 the rook of \mathcal{T} in $V_2 \setminus \{A'\}$. Denote by $R_{A'}$ and $R_{B'}$ the rooks to be placed at A' and B' , respectively. Define $\mathcal{R} = (\mathcal{T} \setminus \{R_1, R_2, R_3\}) \cup \{R_{A'}, R_{B'}\}$. It is clear from the construction that $[\mathcal{R}]_\sim \in \tilde{\mathcal{R}}_{d-1}(\mathcal{P})$ and $[\mathcal{R}]_\sim \notin \tau(\tilde{\mathcal{R}}_1(\mathcal{P}))$, as required.

Both cases lead to that there exists $[\mathcal{R}]_\sim \in \tilde{\mathcal{R}}_{d-1}(\mathcal{P})$ such that $[\mathcal{R}]_\sim \notin \tau(\tilde{\mathcal{R}}_1(\mathcal{P}))$, that is, $\tilde{r}_1(\mathcal{P}) < \tilde{r}_{d-1}(\mathcal{P})$. \square

Proposition 4.3. *Let \mathcal{P} be a collection of cells and $\tilde{r}_{\mathcal{P}}(t) = \sum_{j=0}^d \tilde{r}_j(\mathcal{P}) t^j$ be the switching rook polynomial of \mathcal{P} , where $d = r(\mathcal{P})$. If $\tilde{r}_{\mathcal{P}}(t)$ is palindromic, then \mathcal{P} is domino-stable.*

Proof. We proceed by contradiction, assuming that \mathcal{P} is not domino-stable. Since $\tilde{r}_{\mathcal{P}}(t)$ is palindromic, then $\tilde{r}_d(\mathcal{P}) = 1$. By Proposition 4.2, it must hold that $\tilde{r}_1(\mathcal{P}) < \tilde{r}_{d-1}(\mathcal{P})$, a contradiction. Therefore, \mathcal{P} is domino-stable, as claimed. \square

5. THE MAIN THEOREM AND AN APPLICATION TO GORENSTEIN INNER 2-MINOR IDEALS

In this section, we present the main theorem of the paper, which provides a complete characterization of the palindromicity of switching rook polynomials in terms of the geometry of the related collections of cells.

Theorem 5.1. *Let \mathcal{P} be a collection of cells and $\tilde{r}_{\mathcal{P}}(t)$ be the switching rook polynomial of \mathcal{P} . Then, $\tilde{r}_{\mathcal{P}}(t)$ is palindromic if and only if \mathcal{P} is domino-stable.*

Proof. This result follows directly from Propositions 3.2 and 4.3. \square

A natural application of Theorem 5.1 arises in combinatorial commutative algebra. In [24], the Gorenstein property of a K -algebra is discussed in terms of the palindromicity of its associated h -polynomial. Let us briefly recall the definition of h -polynomial of a K -algebra.

Let R be a polynomial ring over a field K and I be a homogeneous ideal of R . Then R/I has a natural structure of graded K -algebra as $\bigoplus_{k \in \mathbb{N}} (R/I)_k$. The formal power series $\text{HP}_{R/I}(t) = \sum_{k \in \mathbb{N}} \dim_K(R/I)_k t^k$ is called the *Hilbert-Poincaré series* of R/I , and by the Hilbert-Serre Theorem we can write $\text{HP}_{R/I}(t) = \frac{h(t)}{(1-t)^d}$, where $h(t) \in \mathbb{Z}[t]$ with $h(1) \neq 0$ and d is the Krull dimension of R/I . The polynomial $h(t)$ is called the *h -polynomial* of R/I .

For our intention, the results in [24] can be summarized in the following theorem.

Theorem 5.2 (R. Stanley). *Let R be a G -algebra.*

- (1) *If R is Gorenstein, then the h -polynomial of R is palindromic ([24, Theorem 4.1]).*
- (2) *Suppose that R is a Cohen-Macaulay domain. Then, R is Gorenstein if and only if the h -polynomial of R is palindromic ([24, Theorem 4.4]).*

The switching rook polynomial of a collection of cells \mathcal{P} is expected to provide a combinatorial description of the h -polynomial of the coordinate ring of the so-called *inner 2-minor ideal* of \mathcal{P} ([18, Conjecture 2.4]). This binomial ideal was introduced for the first time in [19]. We now recall the construction.

Let \mathcal{P} be a collection of cells, and let $S_{\mathcal{P}} = K[x_v \mid v \in V(\mathcal{P})]$ be the polynomial ring associated with \mathcal{P} , where K is a field. A proper interval $[a, b]$ is called an *inner interval* of \mathcal{P} if all cells in $\mathcal{R}([a, b])$ belong to \mathcal{P} . If $[a, b]$ is an inner interval of \mathcal{P} , with diagonal corners a and b and anti-diagonal corners c and d , then the binomial $x_a x_b - x_c x_d$ is called an *inner 2-minor* of \mathcal{P} . The ideal $I_{\mathcal{P}}$ of $S_{\mathcal{P}}$ generated by all inner 2-minors of \mathcal{P} is called the *ideal of 2-minors* of \mathcal{P} . The quotient ring $K[\mathcal{P}] = S_{\mathcal{P}}/I_{\mathcal{P}}$ is called the *coordinate ring* of \mathcal{P} .

As an application of Theorem 5.1, combined with Theorem 5.2, we obtain the following immediate result.

Corollary 5.3. *Let \mathcal{P} be a collection of cells such that $h_{K[\mathcal{P}]}(t) = \tilde{r}_{\mathcal{P}}(t)$.*

- (1) *If $K[\mathcal{P}]$ is Gorenstein, then \mathcal{P} is domino-stable;*
- (2) *Suppose that $K[\mathcal{P}]$ is a Cohen-Macaulay domain, then the converse of (1) is true: that is, if \mathcal{P} is domino-stable, then $K[\mathcal{P}]$ is Gorenstein.*

To highlight the scope of Corollary 5.3, we present the following example.

Example 5.4. In [21] it was proven that if \mathcal{P} is a simple polyomino (that is, a polyomino without holes), then $K[\mathcal{P}]$ is a normal Cohen-Macaulay domain. In particular, for a parallelogram polyomino \mathcal{P} (a special class of simple polyominoes that can be viewed as a planar distributive lattice when regarded as a poset) [20, Theorem 3.5] shows that $h_{K[\mathcal{P}]}(t) = \tilde{r}_{\mathcal{P}}(t)$. Hence, Corollary 5.3 encompasses [20, Theorem 4.10]. From this perspective, domino stability extends the S -property introduced in [20, Definition 4.1]. For example, the polyomino in Figure 6 (A) is domino-stable (and thus its coordinate ring is Gorenstein), but it does not satisfy the S -property. Moreover, parallelogram polyominoes can also be regarded as skew diagrams; in this setting, Theorem 5.1 recovers [1, Corollary 5.16].

Furthermore, in [10] and [18] the question of Gorensteinness was not initially addressed due to its difficulty. Corollary 5.3 now provides such a description: for convex collections of cells considered in [18] via [18, Corollary 4.2], and for frame polyominoes studied in [10] via [10, Proposition 3.2 and Theorem 4.7]. In Figures 6 (A) and (B) we display two polyominoes whose coordinate rings are Gorenstein, while Figure 14 shows an additional example of a frame polyomino with the same property.

FIGURE 14. A frame polyomino with Gorenstein coordinate ring.

The previous corollary motivates us to search for additional geometric conditions on the shape of domino-stable collections of cells that would yield a sufficient criterion for the Gorenstein property. However, the computational evidence suggests a stronger phenomenon: domino-stability alone already appears to be sufficient for the Gorenstein property. By using Theorem 5.1, we can computationally establish the following result.

Proposition 5.5. *Let \mathcal{P} be a domino-stable collection of cells with rank less than or equal to 10 or a domino-stable polyomino with rank less than or equal to 12. Then $K[\mathcal{P}]$ is Gorenstein.*

Proof. Observe that, if \mathcal{P} is a domino-stable collection of cells and $K[\mathcal{P}]$ is a Cohen–Macaulay domain, then by (2) of Corollary 5.3 it follows that $K[\mathcal{P}]$ is also Gorenstein. Then, it is enough to restrict ourselves to the case where $I_{\mathcal{P}}$ is not prime. We implemented scripts in **SageMath** [25] and **Macaulay2** [9], which are available in [16], and here described.

(A) Compute the set L of all collections of cells of rank n (using **SageMath**). The resulting datasets, that is, plain-text files listing all tested collections of cells and polyominoes, are included in [16, **sage**].

(B) We need to verify that, if \mathcal{P} is a domino-stable collection of cells and $K[\mathcal{P}]$ is not a domain, then $K[\mathcal{P}]$ is Gorenstein. For this purpose, we provide a concise **Macaulay2** algorithm (see the file **TestGorenstein.m2** in [16]), which implements the following steps:

- (1) for a given collection of cells \mathcal{P} , it computes the inner 2-minor ideal of \mathcal{P} ;
- (2) it discards the non-prime instances by using the function **binomialIsPrime**, provided in the package **Binomials** ([11]);
- (3) it retains only those with a palindromic h -polynomial, using a short preliminary auxiliary function **isPalindromic**;
- (4) it verifies the Gorenstein property of $K[\mathcal{P}]$, by using **isGorenstein** provided in the package **TorAlgebra** ([3]).

Indeed, filtering out domino-stable collections of cells from the lists of all collections of cells (or polyominoes) of the given ranks reduces to checking the palindromicity of the h -polynomial, by [18, Theorem 2.3] and Theorem 5.1.

(C) For $n \leq 8$ in the case of collections of cells and for $n \leq 11$ in the case of polyominoes, the computations were performed on a standard machine. The cases $n = 9, 10$ for collections of cells and $n = 12$ for polyominoes were verified using the HPC cluster Tosun provided by Sabancı University, due to their high computational complexity. In all tested cases, namely, for $n \leq 10$ in collections of cells and for $n \leq 12$ in polyominoes, the program confirmed the conjectured claim. Tables 1 and 2 summarize the numbers of weakly connected collections and polyominoes we tested, indicating which of them have non-domain or Gorenstein coordinate ring. \square

The previous computational evidence suggests the following conjecture.

Rank	2	3	4	5	6	7	8	9	10
Number weakly connected collections of cells	2	5	22	94	524	3031	18770	118133	758381
Number weakly connected collections of cells whose coordinate ring is not a domain	0	0	1	2	20	135	1080	8149	61834
Number weakly connected collections of cells whose coordinate ring is not a domain and Gorenstein	0	0	1	1	9	39	233	1258	7074

TABLE 1. Number of weakly connected collections of cells up to symmetries.

Rank	2	3	4	5	6	7	8	9	10	11	12
Number of polyominoes	1	2	5	12	35	108	369	1285	4655	17073	63600
Number of polyominoes whose coordinate ring is not a domain	0	0	0	0	0	0	0	2	12	73	388
Number of polyominoes whose coordinate ring is not a domain and Gorenstein	0	0	0	0	0	0	0	0	0	3	4

TABLE 2. Number of polyominoes up to symmetries.

Conjecture 5.6. *Let \mathcal{P} be a collection of cells. Then, the following are equivalent:*

- (1) $K[\mathcal{P}]$ is Gorenstein;
- (2) the h -polynomial of $K[\mathcal{P}]$ is palindromic;
- (3) the switching rook polynomial of \mathcal{P} is palindromic;
- (4) \mathcal{P} is domino-stable.
