(Dated: December 2, 2025)

We introduce a minimal Dark Standard Model (DSM) consisting of a single spin-0 particle with dark  $U(1)$  gauge symmetry, and completely decoupled from the visible sector. Characterized only by the scalar mass  $\mu$  and the dark charge  $q$ , this framework naturally gives rise to a rich phenomenology, including stable solitonic configurations that behave as dark “mini-MACHOs”. We numerically build and evolve these gauged scalar-field solitons, derive their mass-radius relations, and identify a critical charge beyond which no gravitationally bound configurations exist. By combining these results with microlensing surveys that exclude compact objects heavier than the asteroid-mass scale ( $M \lesssim 10^{-11} M_\odot$ ), we obtain the constraint  $\mu \gtrsim 10$  eV for viable configurations, depending on  $q$ . Our results represent a step forward in showing that purely gravitational observations can constrain the internal parameters of a dark gauge sector, and provide a framework for exploring broader DSM scenarios through future probes such as gravitational wave detections.

## I. INTRODUCTION

The discovery of dark matter (DM) through its gravitational interaction with visible matter has been confirmed at galactic [1–4] and cosmological scales [5–11]. The compelling evidence for the existence of dark matter has driven the development of terrestrial experiments pursuing its direct or indirect detection [12, 13]. Terrestrial experimental searches need to assume a coupling of the DM candidate to visible matter beyond a pure gravitational interaction in order to get a detection signal. While this experimental approach may eventually detect dark matter, current observations imply that there is no empirical evidence that DM couples with standard model (SM) particles [14–24]. In this scenario, an even more elusive possibility arises: that multiple dark matter particles could exist, none of them coupled to those of the SM.

We explore the possibility that dark matter may be composed of distinct particle fields preserving local gauge symmetries, mediated by their own gauge mediators, in analogy with the Standard Model (SM). These fields are minimally coupled to gravity but fully decoupled from SM. We refer to this scenario as the Dark Standard Model, DSM. If such DSM exists, several questions arise: i) what is its particle content?; ii) What gauge symmetries dictate the dynamics of DM interactions?; and, most challenging, iii) how could we experimentally probe the DSM and its associated dark symmetries? As a step forward in addressing these questions, we consider a minimal realization of the DSM consisting of a spin-0 particle with an internal  $U(1)$  gauge symmetry. This represents a textbook example of a gauge theory that has the lowest number of free parameters: the scalar mass  $\mu$  and the charge  $q$ .

Despite having only two parameters, this DSM has a rich phenomenology. For instance, when  $q = 0$  and for

masses  $\mu$  of the order of  $10^{-22}$  eV, the model reduces to the Scalar Field Dark Matter (SFDM) scenario, also known as Fuzzy Dark Matter Model, which successfully reproduces the Cold Dark Matter (CDM) at cosmological scales and, at galactic scales, and may alleviate small-scale (central halo regions) CDM tensions [25, 26].

While the SFDM scenario focuses on wave-like dark matter behavior, scalar fields can also behave as particle-like, compact configurations. In this scenario, they can also be used within the CDM model, which considers that dark matter is composed of non-interactive particles [27], and these particles can be regarded as scalar-field objects. Moreover, microlensing studies [28–30] imply that, if the galactic halos are composed of clusters of massive objects, they cannot have a mass larger than  $10^{-11} M_\odot$ , often referred to as mini-MACHOs. Previous studies with scalar field compact objects (see e.g. [31–33]) showed that galactic halos could be modeled as collisionless ensembles of scalar field MACHOs with masses below than  $10^{-7} M_\odot$ , which was the upper limit at that time.

Within this point of view, we show that for  $\mu \simeq 1$  eV, self-gravitating scalar field configurations have masses around  $10^{-11} M_\odot$  and can play the role of massive compact halo objects (MACHOs). In such a scenario, the halo dynamics would be indistinguishable from that in a CDM halo, since N-body simulations of CDM are insensitive to particle mass granularity smaller than  $10^5 M_\odot$  [27]. These scalar field mini-MACHOs could have formed in the early Universe via a mechanism analogous to the Affleck-Dine Mechanism known in particle physics [34].

Static, spherically symmetric, self-gravitating systems minimally coupled to a scalar field with  $U(1)$  gauge symmetry, known as charged boson stars, have been described in [35–38]. Recently, the dynamics of these self-gravitating configurations was extensively studied in [39]. In this work, we reinterpret these configurations as dark matter structures within the DSM framework. The re-

sulting solutions are everywhere regular and horizonless, representing solitonic equilibria of the model. In contrast, black hole configurations with nontrivial scalar field profiles exist only for self-interacting scalars under specific resonance conditions [40, 41]. Such solutions can be continuously connected to the self-interacting (Q-ball-like) boson star sequence when a small event horizon is introduced. However, full 3+1 numerical evolutions show that they develop a non-axisymmetric instability [42], while their horizonless counterparts remain stable [39]. Therefore, within this theory, the viable static gravitational solitons that could serve as MACHO dark matter candidates are the Reissner–Nordström black holes and the gauged boson stars. Throughout the paper we adopt geometric units ( $c = 1 = G$ ) except where stated otherwise. In this units, the coupling parameter  $q$  then has units of inverse length and can be normalized by the scalar field mass  $\mu$ , so that ratio  $q/\mu$  becomes dimensionless.

## II. GAUGE DARK MATTER SOLITONS

The action for the minimal DSM model is

$$S = \int d^4x \sqrt{-g} \left[ \frac{1}{16\pi} R - g^{\alpha\nu} \mathcal{D}_\alpha \Phi \mathcal{D}_\nu \Phi^* - \mu^2 |\Phi|^2 - \frac{1}{4} F_{\alpha\nu} F^{\alpha\nu} \right], \quad (1)$$

where  $\mu$  is the mass of the spin-0 particle,  $F_{\alpha\nu} = \partial_\alpha A_\nu - \partial_\nu A_\alpha$ ,  $g_{\alpha\nu}$  is the spacetime metric,  $R$  the Ricci scalar. Here  $A_\nu$  is the four-potential. Notice that we use the gauge invariant covariant derivative operator defined as  $\mathcal{D}_\alpha = \nabla_\alpha + i q A_\alpha$ , where  $q$  is the gauge coupling constant or the scalar field charge [39].

Variation with respect to  $g_{\alpha\nu}$  leads to the Einstein field equations, with the stress energy tensor given by

$$T_{\alpha\nu} = 2\mathcal{D}_\alpha \Phi \mathcal{D}_\nu \Phi^* - g_{\alpha\nu} (\mathcal{D}^\beta \Phi \mathcal{D}_\beta \Phi^* + \mu^2 |\Phi|^2) + F_{\alpha\sigma} F_{\nu\lambda} g^{\sigma\lambda} - \frac{1}{4} g_{\alpha\nu} F_{\sigma\beta} F^{\sigma\beta}. \quad (2)$$

Variation with respect to  $A_\alpha$  leads to the Maxwell equations sourced by the spin-0 current  $J^\alpha$ ,

$$\nabla_\nu F^{\alpha\nu} = J^\alpha := q J_\Phi^\alpha, \quad (3a)$$

$$J_\Phi^\alpha := i (\Phi^* \mathcal{D}^\alpha \Phi - \Phi \mathcal{D}^\alpha \Phi^*), \quad (3b)$$

here  $J_\Phi^\alpha$  is the conserved current that arises from the U(1) gauge invariance of Eq. (1). Finally, variation with respect  $\Phi$  leads to the Klein-Gordon equation

$$\mathcal{D}^\alpha \mathcal{D}_\alpha \Phi = \mu^2 \Phi. \quad (4)$$

The minimal energy, self-gravitating realization of model in Eq. (1) is a static spherically symmetric space-time with a stationary scalar field spherical solutions,<sup>1</sup> characterized by a harmonic time dependence of the

FIG. 1. Gauge dark matter solitons sequence of solutions. Top panel: Mass vs. radius diagram for families of configurations with different values of  $q$ . Dashed-line displays the maximum mass configurations. Lower panel: Maximum mass configuration as a function of  $q$  in the region where gravitationally bound, and stable configurations exist. Beyond the critical  $\tilde{q}_{\text{crit}} = 1/\sqrt{2} \approx 0.707$ , no gravitationally bound solutions are found.

scalar field of the form  $\Phi = \phi(r)e^{i\omega t}$  and an “electric” potential  $A_\alpha dx^\alpha = V(r)dt$ . We choose coordinates in which the spacetime metric takes the form

$$ds^2 = -e^{2F_0(r)} dt^2 + e^{2F_1(r)} (dr^2 + r^2 d\Omega^2), \quad (5)$$

with  $d\Omega^2 = d\theta^2 + r^2 \sin^2 \theta d\varphi^2$  the solid angle. Notice that the metric is isotropic.

Under these assumptions for the spacetime and the spin-0 and spin-1 fields, the system reduces to four coupled ordinary differential equations for the functions  $V(r)$ ,  $\phi(r)$ ,  $F_0(r)$  and  $F_1(r)$ , see e.g. Appendix B in [39]. We solve the system numerically, noting first that the mass of the scalar field  $\mu$  can be factored out as the characteristic length scale of the system, and all dimensional quantities rescale with appropriate powers  $\mu$ . We solve the system using a spectral method with a compactified radial coordinate  $r$  and a Newton-Raphson algorithm, as described in [43], and employ 24 spectral coefficients for all solutions presented. In the process, the eigenfrequency of the spin-0 field  $\omega$  is determined as part of the solution. The equilibrium configurations obtained in this scenario form sequences characterized by the coupling constant  $q$ , which has an upper bound of approximately  $q = \sqrt{4\pi\mu}$  that is limited by Coulomb repulsion [35, 37, 38, 44–46]. Following previous literature [35, 38], we present results in terms of the dimensionless rescaled charge  $\tilde{q} = q/(\sqrt{8\pi\mu})$ , for which the critical value is  $\tilde{q}_{\text{crit}} = 1/\sqrt{2}$ . For the solitons considered here, the cen-

<sup>1</sup> Often referred as charged boson stars (see e.g. [35]).

TABLE I. Gauge dark matter solitons: configurations of maximum mass as a function of the rescaled coupling  $\tilde{q}$ . We list the dimensionless rescaled charge  $\tilde{q}$ , the eigenfrequency frequency of the the spin-0 field  $\omega$ , the maximum value of the scalar field at the origin  $\phi(r=0)$ , the mass  $\mu M$ , the total electrical charge  $\mu Q_E$ , and the radius  $\mu R_s$  of the configurations. The critical value  $\tilde{q}_{\text{crit}} = 1/\sqrt{2} \approx 0.707$  marks the limit beyond which no gravitationally bound solutions exist.

$\tilde{q}$	$\omega/\mu$	$\phi(r=0)$	$\mu M$	$\mu Q_E$	$\mu R_s$
0	0.8530	0.0765	0.6330	0	3.816
0.7	0.9958	0.0158	5.203	30.96	22.86
0.705	0.9987	0.00871	9.567	57.69	41.71

tral amplitude of the scalar field parametrizes each sequence of solutions. The top panel of Fig. 1 shows some sequences for several values of  $q$ . Here  $M$  denotes to the total mass of the configuration, obtained from the asymptotic behavior of the metric coefficients:

$$M = - \lim_{r \rightarrow \infty} \left( r^2 \frac{dF_1}{dr} \right), \quad (6)$$

from the  $g_{rr}$  component, or

$$M = \lim_{r \rightarrow \infty} \left( r^2 \frac{dF_0}{dr} \right), \quad (7)$$

from the  $g_{tt}$  component. Both should coincide and we use this two quantities to asses accuracy of the code. The first definition corresponding to the Arnowitt–Deser–Misner (ADM) mass, while the second corresponds to the Komar mass (see e.g. [44, 47, 48]). Following [43], the radius of the configuration is defined as the areal radius  $R$  where  $C := M(R)/R = e^{-F_1} M(r)/r$  is maximized. Here  $M(r)$  denotes the Misner-Sharp function, which in isotropic coordinates is  $M(r) = -r^2 e^{F_1} \partial_r F_1 (1 + r \partial_r F_1/2)$ . The conserved charge  $Q$  associated with the conserved current  $J_\Phi^\alpha$  in Eq. (3b), is given by

$$Q = 4\pi \int_0^\infty e^{3F_1 - F_0} r^2 \phi^2 (Vq + \omega) dr, \quad (8)$$

which is related to the total “electrical” charge  $Q_E$  of the soliton through  $Q_E = qQ$ . Far from the source, the electric potential decays as

$$V(r) = -\frac{Q_E}{4\pi r} + \mathcal{O}\left(\frac{1}{r^2}\right), \quad (9)$$

which we again use to check accuracy of our numerical solutions. We have checked that the relative differences between the ADM and Komar masses, as well as between the two charge definitions, are below  $10^{-4}$ .

Note that the total charge  $Q$  has no definite sign, as it depends on the product of the gauge coupling  $q$ , which is fixed in sign, and  $\omega$ , which can be either positive or negative. The Maxwell Eqs. given by Eq. (3) is invariant under  $(\omega, A_\alpha) \rightarrow (-\omega, -A_\alpha)$ , implying that once the parameter  $q$  is fixed, a change in the sign of  $\omega$  reverses the total electrical charge, as seen from Eq. (8).

FIG. 2. Summary of current microlensing limits on MACHO dark matter fraction as a function of lens mass. The solid black lines mark the 95% confidence level exclusion boundaries from recent surveys: Niikura et al. [49] covers the sub-lunar window around  $10^{-11} - 10^{-6} M_\odot$ , Smyth et al. [50] covers the Earth–Jupiter range  $10^{-6} - 10^{-3} M_\odot$ , Wyrzykowski et al. [51] covers the stellar range  $\sim 10^{-1} - 10 M_\odot$ , and Blaineau et al. [52] covers the intermediate range  $10 - 10^3 M_\odot$ . The red-shaded regions within these curves are excluded.

Fig. 1 shows that, for each value of  $q$ , there is a maximum value of  $M$  (dashed-line in the top panel) that increases with  $q$ . Table I lists additional properties of the corresponding dark-matter solitons, including their radius  $R_s$ , and total charge  $Q_E$ . Stability analysis, both perturbative [36] and non-perturbative [38, 39], have concluded that, configurations with radii larger than that of the maximum mass configurations are stable. Therefore, all configurations on the right side of the maximum (see top panel of Fig. 1) remain stable, while those to the left side are unstable: they either collapse to a black hole, relax into a lower-mass equilibrium state, or disperse. The lower panel of Fig. 1 shows  $M_{\text{max}}$  as a function of the coupling parameter  $q$  in the range  $[0, 0.705]$ . Configurations beyond the critical charge value  $\tilde{q}_{\text{crit}} = 1/\sqrt{2} \approx 0.707$  were found to be gravitationally unbound and therefore unstable. In summary, for each value of  $q$ , there exist a sequence of solutions. If  $q < q_{\text{crit}}$ , a global maximum-mass configuration separates the stable from the unstable branch. These numerical results constrain the dimensionless quantity  $\mu M$  as function of  $q$  (see lower panel of Fig. 1).

In the next section, we use microlensing limits on MACHOs to further constrain the allowed values of  $M$ , and consequently the parameters  $\mu$  and  $q$ .

### III. CONSTRAINTS ON THE FREE $\mu$ AND $q$ FROM MICROLENSING LIMITS

Current microlensing observations have imposed tight constraints on the fraction of dark matter that may be due to MACHOs. As summarized in Fig. 2, these limits depend on the mass of the compact objects  $\mathcal{M}$ . Microlensing observations have effectively exclude MACHOs with  $\mathcal{M} > 10^{-11} M_\odot$  as the dominant dark matter.

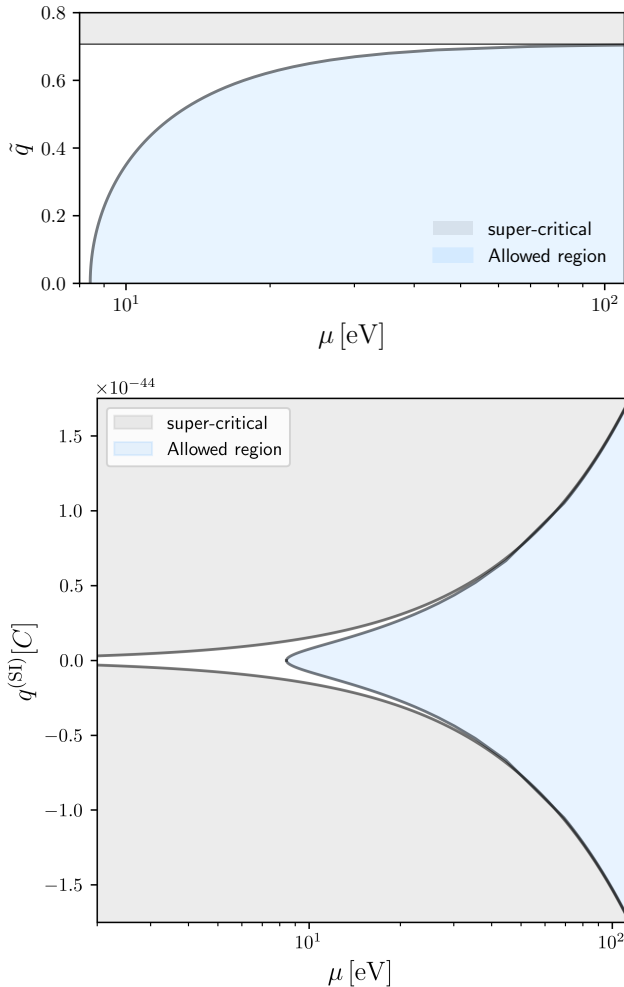

FIG. 3. Constraints in the plane  $(\mu, q)$  parameter space derived from the non-observation of microlensing events. The shaded region indicates the values of the scalar-field mass  $\mu$  and coupling  $q$  consistent with current MACHO limits. Larger masses are excluded by Eq. (11).

In the sub-lunar to Earth-mass range ( $10^{-11} \lesssim \mathcal{M}/M_\odot \lesssim 10^{-6}$ ), the Subaru Hyper Suprime-Cam (HSC) survey of M31 by Niikura et al. [49] detected only one candidate event, placing strong upper limits on the MACHO fraction of dark matter and effectively closing the so-called “lunar-mass window”. At lower masses ( $10^{-16} \lesssim \mathcal{M}/M_\odot \lesssim 10^{-10}$ ), Smyth et al. [50] reanalyzed the same HSC data, incorporating finite-source-size effects. They found that these effects significantly weaken constraints at the smallest masses, suggesting that asteroid-mass MACHOs could still constitute all of the dark matter. At solar masses and above, OGLE observations toward the Magellanic Clouds, particularly those by Wyrzykowski et al. [51], show that the detected microlensing events are consistent with known stellar populations, thereby ruling out MACHOs with  $\mathcal{M} \sim 0.1 - 10 M_\odot$  as more than a small fraction of the dark halo. For heavier objects in the intermediate range ( $\mathcal{M} \sim 10 - 10^3 M_\odot$ ), Blaineau et al. [52] combined MACHO and EROS datasets, finding that such black hole-like MACHOs can account for at most about 15%–50% of the dark matter, depending on mass.

Overall, microlensing surveys have largely ruled out MACHOs as the dominant form of dark matter, leaving room primarily for mini-MACHOs in the asteroid-mass regime.

We model MACHOs using the gauge dark matter solitons described in the previous section and show how microlensing limits constrain the parameters  $\mu$  and  $q$ . For a fixed  $q$ , we numerically obtain a maximum value of  $\mu M$ , a consequence of the self-gravitating nature of the solitons in the minimal gauge dark matter mode in Eq. (1) [53].

From the above observational constraints, MACHO masses must satisfy

$$\mathcal{M} \lesssim 10^{-11} M_\odot = 1.48 \times 10^{-8} \text{m}. \quad (10)$$

Therefore, we require that the maximum mass of the solitonic configurations in Eq.(1) not exceed this bound, i.e.

$$M_{\text{max}} < 1.48 \times 10^{-8} \text{m}. \quad (11)$$

Otherwise, stable solutions exceeding this bound would have masses already ruled out by current microlensing limits. This condition imposes a constraint on the scalar-field mass  $\mu$ :

$$\mu > 6.76 \times 10^7 x(q) \text{m}^{-1} = 13.3x(q)\text{eV} \quad (12)$$

where  $x(q) = \mu M_{\text{max}}$  is obtained from the numerical sequences shown in the lower panel of Fig. 1, or from some specific configurations in Table I. The corresponding constraints on  $\mu$  as function of  $q$  are displayed in the top panel of Fig. 3. In the lower panel, we also show the resulting allowed region with the coupling constant given in SI units, using the conversion

$$q^{(\text{SI})} = \frac{\sqrt{8\pi G\hbar}}{c^2 \sqrt{\mu_0}} \mu \tilde{q} = 2.167 \times 10^{-46} \left( \frac{\mu}{\text{eV}} \right) \tilde{q} \text{C}, \quad (13)$$

where  $G$  is Newton’s gravitational constant,  $\hbar$  the reduced Planck constant,  $c$  the speed of light in vacuum, and  $\mu_0$  the vacuum permeability.

The above results identify a narrow region in the parameter space where gravitationally bound, stable solitons remain compatible with current microlensing constraints. In particular, microlensing non-detections restrict the dark scalar sector to relatively heavy field masses and small gauge couplings, defining a narrow window of viable mini-MACHO configurations within the DSM framework.

#### IV. CONCLUSIONS

The dynamics of visible matter on both galactic and cosmological scales have implications for the existence of dark matter through their gravitational interaction. To date, there is no experimental evidence that dark matter interacts with visible matter through any force other than gravity. However, it is possible that the dark matter sector is not composed of a single particle, but instead forms a self-consistent dark analogue of the Standard Model with its own gauge interactions.

We introduced a minimal Dark Standard Model with a dark  $U(1)$  gauge symmetry, giving rise to solitonic “mini-MACHOs.” We have presented this scalar field model

not as fuzzy dark matter, but within the CDM framework, where dark matter consists of non-interactive particles. We showed that these particles could be composed of a scalar field, whose rest mass must be greater than 10 eV, with more restrictive constraints for a non-zero dark charge.

By combining our derived mass-radius relations for these solitons with microlensing constraints on asteroid-mass objects, we obtain a lower bound of  $\gtrsim 10$  eV on the scalar mass  $\mu$ . We derived this bound from the non-observation of microlensing events, combined with the general properties of gauged scalar field stars. Our main results are summarized in Fig. 3, where, for each value of the gauge coupling  $q$ , we identify a corresponding minimum allowed scalar-field mass. In particular, for  $q = 0$ , the bound is of order 10 eV.

From Fig. 3, one may conclude that current microlensing observations impose a lower limit on the scalar-field mass  $\mu$ , while the gauge coupling  $q$  is restricted by the theoretical condition  $\tilde{q} < \tilde{q}_{\text{crit}} = 1/\sqrt{2}$ , which ensures the existence of gravitationally bound equilibrium configurations. Only sufficiently heavy fields can form compact objects compatible with current surveys. This shifts the viable parameter space of the minimal DSM to  $\mu$ -values well above the ultralight fuzzy/axion-like regime.

These configurations are everywhere regular and horizonless, forming dynamically stable solitonic equilibria of the model in Eq. (1). In contrast, as mentioned above, black hole counterparts with nontrivial scalar hair arise only in self-interacting theories under specific resonance conditions and are unstable. Therefore, within the considered framework, the viable static gravitational solitons consistent with current astrophysical constraints are the Reissner-Nordström black holes and the gauged boson stars, the latter standing as natural, stable MACHO dark matter candidates. The limits we have derived on the scalar field mass could also be affected by considering additional terms in the scalar potential, such as a self-interaction.

The dark matter model proposed in this work also opens new directions for exploring its potential observational signatures. Collisions or mergers of these dark

asteroids could contribute to a stochastic gravitational wave background with distinctive spectral features, as discussed previously (see e.g. [54–58]). Furthermore, the accretion of such dark compact objects onto black holes could endow Reissner-Nordström and Kerr-Newman geometries with an effective dark charge, providing a novel physical interpretation of the charge parameter in these solutions. This perspective could be applied in other contexts where the conventional view has been used, such as to matter in the vicinity of black holes. This possibility motivates further studies of geodesic motion and observable effects in such spacetimes, following the approaches developed in [59–61].

Within this scenario, there are multiple other possibilities that can be studied with different gauge mediators and dark matter particles. These bounds are expected to hold in more general dark-gauge sectors with additional fields or interactions. Given the opening of new observational tools and experiments that probe the Universe through gravitational interactions, such as gravitational wave observations, it now seems possible to begin the systematic study of a dark matter standard model along the lines described in this work, potentially connecting gravitational phenomena to the internal structure of the dark sector.
