### TWO VARIATIONS ON THE XTRACE ALGORITHM

### ERIC HALLMAN\*

Abstract: This paper studies two potential modifications of XTrace (Epperly et al., SIMAX 45(1):1-23, 2024), a randomized algorithm for estimating the trace of a matrix. The first is a variance reduction step that averages the output of XTrace over right-multiplications of the test vectors by random orthogonal matrices. The second is to form a low-rank approximation to the matrix using the whole Krylov space produced by the test vectors, rather than the output of a single power iteration as is used by XTrace. Experiments on synthetic data show that the first modification offers only slight benefits in practice, while the second can lead to significant improvements depending on the spectrum of the matrix.

1. Introduction. We'd like to estimate the trace of a matrix  $\mathbf{A} \in \mathbb{R}^{N \times N}$  which can be accessed only via matrix-vector products (matvecs)  $\boldsymbol{\omega} \mapsto \mathbf{A} \boldsymbol{\omega}$ . One simple method is to use the Girard-Hutchinson estimator [5]: if  $\boldsymbol{\omega}$  satisfies  $\mathbb{E}[\boldsymbol{\omega} \boldsymbol{\omega}^T] = \mathbf{I}_N$ , then

$$\mathbb{E}[\boldsymbol{\omega}^T \mathbf{A} \boldsymbol{\omega}] = \mathbb{E}[\operatorname{tr}(\mathbf{A} \boldsymbol{\omega} \boldsymbol{\omega}^T)] = \operatorname{tr}(\mathbf{A} \cdot \mathbb{E}[\boldsymbol{\omega} \boldsymbol{\omega}^T]) = \operatorname{tr}(\mathbf{A}).$$

More sophisticated methods reduce the variance of the estimator by constructing a low-rank approximation  $\mathbf{A} \approx \mathbf{Q} \mathbf{Q}^T \mathbf{A}$  and using the identity

$$\mathrm{tr}(\mathbf{A}) = \mathrm{tr}(\mathbf{Q}^T\mathbf{A}\mathbf{Q}) + \mathbb{E}[\boldsymbol{\omega}^T(\mathbf{I} - \mathbf{Q}\mathbf{Q}^T)\mathbf{A}(\mathbf{I} - \mathbf{Q}\mathbf{Q}^T)\boldsymbol{\omega}].$$

For a little extra variance reduction, Epperly et al. [2] recommend a normalization step: first, draw the vectors from a spherically symmetric distribution such as  $\boldsymbol{\omega} \sim \mathcal{N}(\mathbf{0}, \mathbf{I}_N)$ . Then, rescale the vectors  $(\mathbf{I} - \mathbf{Q}\mathbf{Q}^T)\boldsymbol{\omega}$  to have norm  $\sqrt{N - \text{rank}(\mathbf{Q})}$ .

Meyer et al. [8] showed that when  $\mathbf{A}$  is positive definite, it suffices to compute  $\mathbf{Q}$  from a single power iteration  $\mathbf{Q} = \operatorname{orth}(\mathbf{A}\mathbf{\Omega})$ . However, to naïvely use the same set of test vectors  $\mathbf{\Omega}$  for both the low-rank approximation  $\mathbf{Q}$  and the Girard-Hutchinson estimator would produce a biased estimate. One solution is to use different sets of test vectors  $\mathbf{\Omega}_1$  and  $\mathbf{\Omega}_2$  for each step: in [8, Alg. 1]  $\mathbf{\Omega}_1$  and  $\mathbf{\Omega}_2$  are set to have the same number of columns, and Persson et al. [10] propose an adaptive method to more efficiently allocate the test vectors.

Epperly et al. [2] made the key insight that no such compromise is needed. Their XTrace estimator uses all of the test vectors for both low-rank approximation and the Girard-Hutchinson estimator, using a leave-one-out technique to ensure that the estimator remains unbiased. Algorithm 1.1 provides a simple implementation; the authors also show how to compute each of the bases  $\mathbf{Q}_{(i)}$  efficiently so that, for m test vectors, the overall method requires only  $\mathcal{O}(m^2N)$  operations besides the matvecs  $\mathbf{\Omega} \mapsto \mathbf{A}\mathbf{\Omega}$ .

- 1.1. Contributions. This paper proposes two modifications to the XTrace estimator that will further reduce its variance without adding bias.
  - 1. Average the output of XTrace over multiple random rotations  $\Omega \mapsto \Omega U$ .
- 2. Orthogonalize each  $\omega_i$  against  $[(\mathbf{A}\Omega)_{-i}, \Omega_{-i}]$ , not just  $(\mathbf{A}\Omega)_{-i}$ . Neither of these proposals requires any additional matvecs with  $\mathbf{A}$ .

## Algorithm 1.1 XTrace: naïve implementation (with normalization) [2]

**Input:** Matrix  $\mathbf{A} \in \mathbb{R}^{N \times N}$ ; number of test vectors m

Output: Approximation to tr(A)

```
1: Sample i.i.d. \omega_1, \ldots, \omega_m \sim \mathcal{N}(\mathbf{0}, \mathbf{I}_N)
2: \mathbf{Y} = \mathbf{A}\mathbf{\Omega}
                                                                                                                                                                                    \{\mathbf{\Omega} = [\boldsymbol{\omega}_1, \dots, \boldsymbol{\omega}_m]\}
3: for i = 1, 2, ..., m do
             Compute an orthonormal basis \mathbf{Q}_{(i)} for \mathbf{Y}_{-i}
                                                                                                                                                              {Remove ith column of \mathbf{Y}}
          \begin{aligned} & \boldsymbol{\mu} = (\mathbf{I} - \mathbf{Q}_{(i)} \mathbf{Q}_{(i)}^T) \boldsymbol{\omega}_i \\ & \boldsymbol{\nu} = \sqrt{N - \mathrm{rank}(\mathbf{Q}_{(i)})} \cdot \boldsymbol{\mu} / \|\boldsymbol{\mu}\|_2 \end{aligned}
                                                                                                                                                                                             {Normalization}
         \widehat{\operatorname{tr}}_i = \operatorname{tr}(\mathbf{Q}_{(i)}^T \mathbf{A} \mathbf{Q}_{(i)}) + \boldsymbol{
u}^T \mathbf{A} \boldsymbol{
u}
8: end for
9: return \frac{1}{m} \sum_{i=1}^{m} \widehat{\operatorname{tr}}_i
```

We also consider the more general question: what invariance properties must an optimal trace estimator have? For the purposes of this paper, a trace estimator  $\operatorname{est}_{\mathbf{A}}(\cdot)$  could be called "optimal" if it is admissible within the class

(1.1) 
$$\mathcal{F} := \{ g(\mathbf{\Omega}, \mathbf{A}\mathbf{\Omega}, \mathbf{A}^2\mathbf{\Omega}) : \mathbb{E}[g(\mathbf{\Omega}, \mathbf{A}\mathbf{\Omega}, \mathbf{A}^2\mathbf{\Omega})] = \operatorname{tr}(\mathbf{A}) \}.$$

That is,  $\operatorname{est}_{\mathbf{A}}(\cdot) \in \mathcal{F}$ , and there is no other estimator  $\operatorname{est}'_{\mathbf{A}}(\cdot)$  satisfying  $\operatorname{Var}(\operatorname{est}'_{\mathbf{A}}(\Omega)) \leq$  $Var(est_{\mathbf{A}}(\Omega))$  for all  $\mathbf{A}$ , with strict inequality for at least one  $\mathbf{A}$ .

We observe that such an estimator must be basis-invariant in that it can be expressed as a function of  $\mathcal{R}(\Omega)$ , and we show in Theorem 3.5 that our modified algorithm has certain invariance properties that XTrace does not.

### Algorithm 1.2 XTrace-Full: naïve implementation

**Input:** Matrix  $\mathbf{A} \in \mathbb{R}^{N \times N}$ ; number of test vectors m

```
Output: Approximation to tr(A)
  1: Sample i.i.d. \omega_1, \ldots, \omega_m \sim \mathcal{N}(\mathbf{0}, \mathbf{I}_N)
 2: \mathbf{Y} = \mathbf{A}\mathbf{\Omega}
                                                                                                                    \{\mathbf{\Omega} = [\boldsymbol{\omega}_1, \dots, \boldsymbol{\omega}_m]\}
 3: for i = 1, 2, ..., m do
       Compute an orthonormal basis \mathbf{Q}_{(i)} for [\mathbf{Y}_{-i}, \mathbf{\Omega}_{-i}]
       oldsymbol{\mu} = (\mathbf{I} - \mathbf{Q}_{(i)} \mathbf{Q}_{(i)}^T) oldsymbol{\omega}_i
 {Normalization}
 8: end for
 9: return \frac{1}{m} \sum_{i=1}^{m} \widehat{\operatorname{tr}}_{i}
```

1.2. Related work and commentary on optimality conditions. It is worth mentioning that a variety of trace estimators exist that are not in the class of functions defined in (1.1).

First, we could permit biased estimators, comparing them by mean-squared error instead of variance. One such estimator follows from the Variance-reduced Stochastic Lanczos Quadrature proposed by Bhattacharjee et al. [1, Thm. 5], which constructs a Krylov space and deflates sufficiently-converged eigenvalues, resulting in a very small but nonzero bias. More generally, when computing the trace of some matrix function such as  $f(\mathbf{A}) = \mathbf{A}^{-1}$  or  $\exp(\mathbf{A})$ , it is common to approximate the function using Chebyshev polynomials or quadrature. Truly unbiased estimators exist [11], but have not gotten much attention in the literature on trace estimation.

Second, the requirement that  $\mathbf{A}$  be accessible strictly through matvecs precludes probing methods, which in addition to applying matvecs will partition sparse matrices using graph-coloring algorithms (see [4] and the references therein). It also precludes multilevel methods such as in Frommer et al. [3], which are effective when  $f(\mathbf{A})$  can be approximated using a multigrid hierarchy.

Third, we could consider adaptive methods for choosing how to apply the matvecs: given a budget on the number of matvecs, matrix loads, and memory, one could define

$$\operatorname{est}_{\mathbf{A}}(\mathbf{\Omega}) = g(\mathbf{Y}_0, \mathbf{Y}_1, \dots, \mathbf{Y}_{q-1}),$$

where  $\mathbf{Y}_0 = \mathbf{\Omega}$ ,  $\mathbf{Y}_1 = \mathbf{A} \cdot g_1(\mathbf{Y}_0)$ ,  $\mathbf{Y}_2 = \mathbf{A} \cdot g_2(\mathbf{Y}_0, \mathbf{Y}_1)$ , and so on. This function class would be broad enough to accommodate the adaptive method proposed in [10], or the multi-polynomial method in [6] which approximates  $f(\mathbf{A})$  using polynomials of varying degree.

1.3. XTrace is not rotation-invariant. The XTrace estimator is symmetric with respect to the test vectors  $\omega_1, \ldots, \omega_m$ . Epperly et al., citing Halmos [7], note that any minimum-variance unbiased trace estimator must have this property. However, XTrace is not invariant under arbitrary rotations  $\Omega \mapsto \Omega U$ . For a reproducible example, consider the inputs

$$\mathbf{A} = \begin{bmatrix} 5 & 0 & 0 & 0 & 0 \\ 0 & 4 & 0 & 0 & 0 \\ 0 & 0 & 3 & 0 & 0 \\ 0 & 0 & 0 & 2 & 0 \\ 0 & 0 & 0 & 0 & 1 \end{bmatrix}, \quad \mathbf{\Omega} = \begin{bmatrix} 1 & 0 \\ 0 & 1/2 \\ 0 & 1/2 \\ 0 & 1/2 \\ 0 & 1/2 \end{bmatrix}, \quad \mathbf{U}_{\theta} = \begin{bmatrix} \cos \theta & -\sin \theta \\ \sin \theta & \cos \theta \end{bmatrix}.$$

Figure 1.1 shows the output of Algorithm 1.1 when the random samples are replaced by  $\Omega \mathbf{U}_{\theta}$ . As  $\theta$  ranges over  $[0, \pi/2]$ , the trace estimate oscillates. Thus by taking the average output over  $\theta$ , we could obtain an estimator with lower variance.

- 1.4. Organization. The rest of this paper is organized as follows: section 3 discusses the invariance properties of various trace estimators and proposes our modified estimator XTraceFull (Algorithm 1.2). Section 4 derives an efficient implementation (Algorithm 4.1). Section 5 presents the results of some numerical experiments. Section 6 offers concluding remarks and some avenues for future work.
- **2. Notation.** For a matrix  $\mathbf{X}$ ,  $\mathbf{X}_{-i}$  denotes  $\mathbf{X}$  but with the ith column removed and  $\mathcal{R}(\mathbf{X})$  denotes the column space of  $\mathbf{X}$ . The vector  $\mathbf{e}_i$  is the ith standard basis vector.  $\mathbf{X}^{\dagger}$  is the Moore-Penrose inverse, equal to  $(\mathbf{X}^T\mathbf{X})^{-1}\mathbf{X}^T$  when  $\mathbf{X}$  has full column rank.  $\mathbf{X} \otimes \mathbf{Y}$  is the Kronecker product of  $\mathbf{X}$  and  $\mathbf{Y}$ , having (i,j) block entry equal to  $\mathbf{X}_{ij}\mathbf{Y}$ .

A "random orthogonal" matrix always means one sampled from the Haar distribution.  $\mathcal{N}(\mathbf{0}, \mathbf{I}_N)$  is the standard multivariate Gaussian distribution, and  $\chi_N^2$  is the chi-squared distribution with N degrees of freedom.

Fig. 1.1: The output of XTrace is not invariant under arbitrary rotations  $\Omega \mapsto \Omega U$ .

**3. Basis-invariant estimators.** Let  $\operatorname{est}_{\mathbf{A}}(\Omega)$  be a trace estimator with finite variance. The law of total variance states that

$$\operatorname{Var}(\operatorname{est}_{\mathbf{A}}(\Omega)) = \mathbb{E}[\operatorname{Var}(\operatorname{est}_{\mathbf{A}}(\Omega)|\mathcal{R}(\Omega))] + \operatorname{Var}(\mathbb{E}[\operatorname{est}_{\mathbf{A}}(\Omega)|\mathcal{R}(\Omega)]),$$

and the law of total expectation states that

$$\mathbb{E}[\mathbb{E}[\operatorname{est}_{\mathbf{A}}(\Omega)|\mathcal{R}(\Omega)]] = \mathbb{E}[\operatorname{est}_{\mathbf{A}}(\Omega)].$$

Therefore, by conditioning on  $\mathcal{R}(\Omega)$  and taking expectations, we can obtain an estimator with the same expectation and lesser-or-equal variance. Such an estimator is also *basis-invariant*: it depends only on  $\mathcal{R}(\Omega)$ , and transformations  $\Omega \mapsto \Omega \mathbf{B}$  will not affect the output for any invertible matrix  $\mathbf{B}$ .

When  $\Omega$  has i.i.d. standard Gaussian entries, we can use a standard result about the distributions of such matrices [9] to express the conditional expectation in a cleaner form.

LEMMA 3.1. If  $\Omega \in \mathbb{R}^{N \times m}$  has i.i.d.  $\mathcal{N}(0,1)$  entries, then it has distribution equal to a product of three independent terms QUR, where

- $\mathbf{Q} \in \mathbb{R}^{N \times m}$  has orthonormal columns and is Haar-distributed on the Stiefel manifold  $V_m(\mathbb{R}^N)$ ;
- $\mathbf{U} \in \mathbb{R}^{m \times m}$  is orthogonal and Haar-distributed;
- **R** is upper triangular with independent entries  $\mathbf{R}_{ii} \sim \chi^2_{N-i+1}$ ,  $\mathbf{R}_{ij} \sim \mathcal{N}(0,1)$ , and consequently  $\mathbb{E}[\mathbf{R}^T\mathbf{R}] = N \cdot \mathbf{I}_m$ .

Furthermore, conditioning on  $\mathcal{R}(\Omega)$  is equivalent to conditioning on  $\mathbf{Q}$ .

Thus in principle, we could always estimate  $\mathbb{E}[\operatorname{est}_{\mathbf{A}}(\Omega)|\mathcal{R}(\Omega)]$  by fixing an orthonormal basis  $\mathbf{Q}$  for  $\mathcal{R}(\Omega)$  and repeatedly sampling  $\operatorname{est}_{\mathbf{A}}(\mathbf{QUR})$  for random  $\mathbf{U}$  and  $\mathbf{R}$ . Depending on the estimator, it may be possible to simplify the expression further. In the case of the plain Girard-Hutchinson estimator, for example, we can compute the conditional expectation exactly.

THEOREM 3.2. If  $\Omega \in \mathbb{R}^{N \times m}$  has i.i.d.  $\mathcal{N}(0,1)$  entries and  $\mathbf{Q}$  is any orthonormal

basis for  $\mathcal{R}(\Omega)$ , then

$$\mathbb{E}\left[\frac{1}{m}\operatorname{tr}(\mathbf{\Omega}^T\mathbf{A}\mathbf{\Omega})|\mathcal{R}(\mathbf{Q})\right] = \frac{N}{m}\operatorname{tr}(\mathbf{Q}^T\mathbf{A}\mathbf{Q}).$$

Proof. By Lemma 3.1 and the law of total expectation, we find that

$$\begin{split} \mathbb{E}\left[\frac{1}{m}\operatorname{tr}(\mathbf{\Omega}^{T}\mathbf{A}\mathbf{\Omega})|\mathcal{R}(\mathbf{\Omega})\right] &= \frac{1}{m}\mathbb{E}[\operatorname{tr}(\mathbf{R}^{T}\mathbf{U}^{T}\mathbf{Q}^{T}\mathbf{A}\mathbf{Q}\mathbf{U}\mathbf{R})|\mathbf{Q}] \\ &= \frac{1}{m}\operatorname{tr}(\mathbf{Q}^{T}\mathbf{A}\mathbf{Q} \cdot \mathbb{E}[\mathbf{U}\mathbf{R}\mathbf{R}^{T}\mathbf{U}^{T}]) \\ &= \frac{1}{m}\operatorname{tr}(\mathbf{Q}^{T}\mathbf{A}\mathbf{Q} \cdot \mathbb{E}[\mathbb{E}[\mathbf{U}\mathbf{R}\mathbf{R}^{T}\mathbf{U}^{T}|\mathbf{R}]]) \\ &= \frac{1}{m}\operatorname{tr}\left(\mathbf{Q}^{T}\mathbf{A}\mathbf{Q} \cdot \mathbb{E}\left[\frac{1}{m}\operatorname{tr}(\mathbf{R}\mathbf{R}^{T})\mathbf{I}_{m}\right]\right) \\ &= \frac{1}{m^{2}}\operatorname{tr}\left(\mathbf{Q}^{T}\mathbf{A}\mathbf{Q}\right) \cdot \mathbb{E}\left[\operatorname{tr}(\mathbf{R}^{T}\mathbf{R})\right] \\ &= \frac{1}{m^{2}}\operatorname{tr}\left(\mathbf{Q}^{T}\mathbf{A}\mathbf{Q}\right) \cdot \mathbb{E}\left[\|\mathbf{\Omega}\|_{F}^{2}\right] \\ &= \frac{1}{m}\operatorname{tr}(\mathbf{Q}^{T}\mathbf{A}\mathbf{Q}) \cdot mN \\ &= \frac{N}{m}\operatorname{tr}(\mathbf{Q}^{T}\mathbf{A}\mathbf{Q}). \end{split}$$

In the above, we used the fact that  $\mathbb{E}[\mathbf{U}\mathbf{M}\mathbf{U}^T] = \frac{1}{m}\operatorname{tr}(\mathbf{M})\mathbf{I}_m$  for symmetric  $\mathbf{M}$ , and the linear and cyclic properties of the trace operator.

It is already generally known that first orthogonalizing  $\Omega$  slightly reduces the variance of the Girard-Hutchinson estimator; this proof frames that result in terms of conditional expectations.

**3.1. Application to XTrace.** For XTrace, on the other hand, some numerical experiments suggest that

(3.1) 
$$\mathbb{E}[\mathsf{XTrace}_{\mathbf{A}}(\mathbf{QUR})|\mathbf{Q})] \neq \mathbb{E}[\mathsf{XTrace}_{\mathbf{A}}(\mathbf{QU})|\mathbf{Q})]$$

in general. If so, then there is no result for XTrace exactly analogous to Theorem 3.2 which by taking expectations removes the dependence on  ${\bf R}$  entirely.

There is, however, an analogous result for XTraceFull. To derive it, we introduce Algorithm 3.2 as a computational primitive called LeaveOneOutFull. It uses the first m-1 columns of  $\Omega$  for deflation, and reserves the final column for the Girard-Hutchinson estimator. XTraceFull is then the average of LeaveOneOutFull over all column permutations  $\Omega \mapsto \Omega \Pi$ . Similarly, Algorithm 3.1 describes a computational primitive LeaveOneOut for XTrace.

Lemma 3.3. For orthogonal U and fixed  $\Omega$ , the value of the functions

$$\mathbf{U}\mapsto \mathtt{LeaveOneOutFull}_{\mathbf{A}}(\mathbf{\Omega}\mathbf{U}), \ \mathbf{U}\mapsto \mathtt{LeaveOneOut}_{\mathbf{A}}(\mathbf{\Omega}\mathbf{U})$$

depend only on the final column of U.

*Proof.* Let **u** be the final column of **U**. Since

$$\begin{split} \mathcal{R}\left((\mathbf{A}\boldsymbol{\Omega}\mathbf{U})_{-m}\right) &= \mathcal{R}\left(\mathbf{A}\boldsymbol{\Omega}\mathbf{U}(\mathbf{I} - \mathbf{e}_m\mathbf{e}_m^T)\right) \\ &= \mathcal{R}\left(\mathbf{A}\boldsymbol{\Omega}(\mathbf{I} - \mathbf{u}\mathbf{u}^T)\mathbf{U}\right) \\ &= \mathcal{R}\left(\mathbf{A}\boldsymbol{\Omega}(\mathbf{I} - \mathbf{u}\mathbf{u}^T)\right), \end{split}$$

and similarly for  $\mathcal{R}((\Omega \mathbf{U})_{-m})$ , the range of the orthonormal basis  $\mathbf{Q}$  computed by Algorithm 3.2 or Algorithm 3.1 is determined entirely by  $\mathbf{u}$  for any given  $\mathbf{\Omega}$ . After

that, the algorithms compute

$$\mu = (\mathbf{I} - \mathbf{Q}\mathbf{Q}^T)\mathbf{\Omega}\mathbf{U}\mathbf{e}_m = (\mathbf{I} - \mathbf{Q}\mathbf{Q}^T)\mathbf{\Omega}\mathbf{u},$$

which again depends only on **u**.

Lemma 3.4. For any invertible block upper triangular matrix  $\mathbf{R}$  with block sizes (m-1,1),

$$\mathtt{LeaveOneOutFull}_{\mathbf{A}}(\mathbf{\Omega}) = \mathtt{LeaveOneOutFull}_{\mathbf{A}}(\mathbf{\Omega}\mathbf{R}).$$

This result does not hold for LeaveOneOut.

*Proof.* Algorithm 3.2 effectively computes the unpivoted QR factorization

$$[\mathbf{A}\mathbf{\Omega}_{-m},\,\mathbf{\Omega}]=[\mathbf{Q},\,oldsymbol{\mu}]\widehat{\mathbf{R}}.$$

The transformation  $\Omega \mapsto \Omega \mathbf{R}$  does not alter either  $\mathcal{R}(\mathbf{Q})$  or  $\mathcal{R}(\mu)$ , and so the output of Algorithm 3.2 is unchanged. The same cannot be said of Algorithm 3.1 because

$$\mathcal{R}([\mathbf{A}\mathbf{\Omega}_{-m},\,\mathbf{\Omega}\mathbf{e}_n]) \neq \mathcal{R}([\mathbf{A}\mathbf{\Omega}_{-m},\,\mathbf{\Omega}\mathbf{r}])$$

for general nonzero vectors  $\mathbf{r}$ .

We are now set up to provide our main result about XTraceFull.

THEOREM 3.5. If  $\Omega \in \mathbb{R}^{N \times m}$  has i.i.d.  $\mathcal{N}(0,1)$  entries and  $\mathbf{Q}$  is any orthonormal basis for  $\mathcal{R}(\Omega)$ , then

$$\begin{split} \mathbb{E}[\mathtt{XTraceFull}_{\mathbf{A}}(\mathbf{\Omega})|\mathcal{R}(\mathbf{\Omega})] &= \mathbb{E}[\mathtt{LeaveOneOutFull}_{\mathbf{A}}(\mathbf{QU})|\mathbf{Q}] \\ &= \mathbb{E}[\mathtt{XTraceFull}_{\mathbf{A}}(\mathbf{QU})|\mathbf{Q}], \end{split}$$

for random orthogonal U. The value of LeaveOneOutFull $_{\mathbf{A}}(\mathbf{Q}U)$  depends only on  $\mathbf{Q}$  and the last column of U.

*Proof.* Let  $\Pi$  be a random permutation. Use, in order, the fact that  $\Omega$  and  $\Omega\Pi$  have the same distribution conditional on  $\mathcal{R}(\Omega)$ , Lemma 3.1, and Lemma 3.4:

$$\begin{split} \mathbb{E}[\mathtt{XTraceFull}_{\mathbf{A}}(\Omega)|\mathcal{R}(\Omega)] &= \mathbb{E}[\mathbb{E}[\mathtt{LeaveOneOutFull}_{\mathbf{A}}(\Omega\Pi)|\Omega]|\mathcal{R}(\Omega)] \\ &= \mathbb{E}[\mathtt{LeaveOneOutFull}_{\mathbf{A}}(\Omega)|\mathcal{R}(\Omega)] \\ &= \mathbb{E}[\mathtt{LeaveOneOutFull}_{\mathbf{A}}(\mathbf{QUR})|\mathbf{Q}] \\ &= \mathbb{E}[\mathtt{LeaveOneOutFull}_{\mathbf{A}}(\mathbf{QU})|\mathbf{Q}]. \end{split}$$

The second equality follows from the fact that U and  $U\Pi$  have the same distribution:

$$\begin{split} \mathbb{E}[\mathtt{XTraceFull}_{\mathbf{A}}(\mathbf{Q}\mathbf{U})|\mathbf{Q}] &= \mathbb{E}[\mathbb{E}[\mathtt{LeaveOneOutFull}_{\mathbf{A}}(\mathbf{Q}\mathbf{U}\boldsymbol{\Pi})|\mathbf{Q},\mathbf{U}]|\mathbf{Q}] \\ &= \mathbb{E}[\mathtt{LeaveOneOutFull}_{\mathbf{A}}(\mathbf{Q}\mathbf{U})|\mathbf{Q}]. \end{split}$$

The final claim is just restating the result of Lemma 3.3.

Thus for LeaveOneOutFull, as for the plain Girard-Hutchinson estimator in Theorem 3.2, the expected output conditional on  $\mathcal{R}(\Omega)$  can be expressed in a form that makes no reference to the triangular factor  $\mathbf{R}$ .

- 3.2. Sampling strategies. To compute  $\mathbb{E}[XTraceFull_A(\mathbf{QU})|\mathbf{Q}]$  or estimate it, there are a few options worth considering:
  - Express  $\mathbb{E}[\text{LeaveOneOut}_{\mathbf{A}}(\mathbf{QU})|\mathbf{Q}]$  as an integral over the sphere  $\mathcal{S}^{m-1}$  and compute it via quadrature. This is feasible if the number of test vectors m is very small (say,  $2 \le m \le 4$ ).
  - Approximate  $\mathbb{E}[\text{LeaveOneOut}_{\mathbf{A}}(\mathbf{QU})|\mathbf{Q}]$  by sampling random unit vectors  $\mathbf{u}$ . This will come at a marginal cost of  $\mathcal{O}(m^2)$  operations per sample.
  - Approximate  $\mathbb{E}[\mathtt{XTraceFull}_{\mathbf{A}}(\mathbf{Q}\mathbf{U})|\mathbf{Q}]$  by sampling random orthogonal matrices  $\mathbf{U}$ . It is plausible that orthonormal vectors will yield negatively correlated estimates, which could make up for the added orthogonalization costs compared to sampling vectors independently.
  - Approximate  $\mathbb{E}[\mathsf{XTraceFull}_{\mathbf{A}}(\mathbf{QU})|\mathbf{Q}]$  by starting with  $\mathbf{U} = \mathbf{I}_m$  and transforming it using a sequence of random Givens rotations (Kac's random walk) or Householder reflections.

Implemented properly, the computational cost of any of these methods will be independent of the dimension N of  $\mathbf{A}$ .

# Algorithm 3.1 LeaveOneOut

Input: Matrix  $\mathbf{A} \in \mathbb{R}^{N \times N}$ ; test vectors  $\mathbf{\Omega} \in \mathbb{R}^{N \times m}$ 

Output: Approximation to tr(A)

1: Compute an orthonormal basis  $\mathbf{Q}$  for  $\mathbf{A}\Omega_{-m}$  {Remove last column of  $\mathbf{Y}$ }

2:  $\boldsymbol{\mu} = (\mathbf{I} - \mathbf{Q}\mathbf{Q}^T)\boldsymbol{\Omega}\mathbf{e}_m$ 

3:  $\boldsymbol{\nu} = \sqrt{N - \text{rank}(\mathbf{Q})} \cdot \boldsymbol{\mu} / \|\boldsymbol{\mu}\|_2$  {Normalization}

4: **return**  $tr(\mathbf{Q}^T \mathbf{A} \mathbf{Q}) + \boldsymbol{\nu}^T \mathbf{A} \boldsymbol{\nu}$ 

### Algorithm 3.2 LeaveOneOutFull

Input: Matrix  $\mathbf{A} \in \mathbb{R}^{N \times N}$ ; test vectors  $\mathbf{\Omega} \in \mathbb{R}^{N \times m}$ 

Output: Approximation to tr(A)

1: Compute an orthonormal basis **Q** for  $[\mathbf{A}\Omega_{-m}, \Omega_{-m}]$ 

2:  $\boldsymbol{\mu} = (\mathbf{I} - \mathbf{Q}\mathbf{Q}^T)\boldsymbol{\Omega}\mathbf{e}_m$ 

3:  $\boldsymbol{\nu} = \sqrt{N - \operatorname{rank}(\mathbf{Q})} \cdot \boldsymbol{\mu} / \|\boldsymbol{\mu}\|_2$  {Normalization}

4: **return**  $tr(\mathbf{Q}^T \mathbf{A} \mathbf{Q}) + \boldsymbol{\nu}^T \mathbf{A} \boldsymbol{\nu}$ 

4. Practical implementation. This section will cover how to compute the value of  $LeaveOneOut_A(QU)$  given the last column u of U. The extension to evaluating  $XTraceFull_A(QU)$  given a whole matrix U is straightforward.

First, compute the QR factorization

$$egin{bmatrix} oldsymbol{\Omega} & \mathbf{A} oldsymbol{\Omega} \end{bmatrix} = egin{bmatrix} \mathbf{Q}_0 & \mathbf{Q}_1 \end{bmatrix} egin{bmatrix} \mathbf{R}_0 & \mathbf{M} \ & \mathbf{R}_1 \end{bmatrix},$$

and right-multiply both block columns by  $\mathbf{R}_0^{-1}$  to get the same factorization over a different set of starting vectors,

$$\begin{bmatrix} \mathbf{Q}_0 & \mathbf{A}\mathbf{Q}_0 \end{bmatrix} = \underbrace{\begin{bmatrix} \mathbf{Q}_0 & \mathbf{Q}_1 \end{bmatrix}}_{\mathbf{Q}} \underbrace{\begin{bmatrix} \mathbf{I}_m & \mathbf{M}\mathbf{R}_0^{-1} \\ & \mathbf{R}_1\mathbf{R}_0^{-1} \end{bmatrix}}_{\mathbf{R}}.$$

Given a vector  $\mathbf{u}$ , we'd like to cheaply find an orthonormal basis for the reduced matrix

$$egin{bmatrix} \left[\mathbf{Q}_0(\mathbf{I}-\mathbf{u}\mathbf{u}^\dagger) & \mathbf{A}\mathbf{Q}_0(\mathbf{I}-\mathbf{u}\mathbf{u}^\dagger) 
ight] = \mathbf{Q}\mathbf{R} \left(\mathbf{I}_{2m} - egin{bmatrix} \mathbf{u} & \ & \mathbf{u} \end{bmatrix} egin{bmatrix} \mathbf{u} & \ & \mathbf{u} \end{bmatrix}^\dagger \end{pmatrix}$$

The two vectors removed from the basis can be expressed in the form **QS** for some  $\mathbf{S} \in \mathbb{R}^{2m \times 2}$ , and must satisfy

$$\mathbf{QS} \perp \mathbf{QR} \left( \mathbf{I}_{2m} - egin{bmatrix} \mathbf{u} & \ & \mathbf{u} \end{bmatrix} egin{bmatrix} \mathbf{u} & \ & \mathbf{u} \end{bmatrix}^\dagger 
ight)$$

One solution is given by

$$\mathbf{S} = \mathbf{R}^{-T} \begin{bmatrix} \mathbf{u} & \\ & \mathbf{u} \end{bmatrix}.$$

Specifically, the first and second columns are the vectors that would be left out by removing  $\mathbf{Q}_0\mathbf{u}$  and  $\mathbf{A}\mathbf{Q}_0\mathbf{u}$ , respectively, from  $\begin{bmatrix} \mathbf{Q}_0 & \mathbf{A}\mathbf{Q}_0 \end{bmatrix}$ .

The result **S** does not in general have orthogonal columns, so find the factorization  $\mathbf{S} = \widetilde{\mathbf{S}}\mathbf{L}$ , where **L** is *lower* triangular. Why lower triangular? Because in order to find  $\boldsymbol{\mu}$  in Algorithm 3.2, we effectively want the unpivoted QR factorization

$$egin{bmatrix} \mathbf{Q}_0 \mathbf{U}_{\perp} & \mathbf{A} \mathbf{Q}_0 \mathbf{U}_{\perp} & \mathbf{Q}_0 \mathbf{u} & \mathbf{A} \mathbf{Q}_0 \mathbf{u} \end{bmatrix} = egin{bmatrix} \mathbf{Q}_{(\mathbf{u})} & \boldsymbol{\mu} & \mathbf{Q} \tilde{\mathbf{s}}_2 \end{bmatrix},$$

where  $[\mathbf{U}_{\perp}, \mathbf{u}]$  is orthogonal. The final column  $\mathbf{Q}\tilde{\mathbf{s}}_2$  is the result of orthogonalizing  $\mathbf{A}\mathbf{Q}_0\mathbf{u}$  against all the other columns, and so will be parallel to  $\mathbf{Q}\mathbf{s}_2$ . But we don't want to orthogonalize  $\mathbf{Q}_0\mathbf{u}$  against *all* other columns, just the ones that form  $\mathbf{Q}_{(\mathbf{u})}$ . So to find  $\boldsymbol{\mu}$  (parallel to  $\mathbf{Q}\tilde{\mathbf{s}}_1$ ), we have to orthogonalize  $\mathbf{s}_1$  against  $\tilde{\mathbf{s}}_2$ .

Now to compute the trace estimate. As a preprocessing step, define

$$\mathbf{H} := \mathbf{Q}^T \mathbf{A} \mathbf{Q},$$

noting that the first m columns of  $\mathbf{H}$  were already computed in (4.1). We then find that

$$\begin{split} \widehat{\operatorname{tr}}_{\mathbf{u}} &= \operatorname{tr}(\mathbf{Q}_{(\mathbf{u})}^T \mathbf{A} \mathbf{Q}_{(\mathbf{u})}) + \boldsymbol{\nu}^T \mathbf{A} \boldsymbol{\nu} \\ &= \operatorname{tr}\left(\mathbf{A} \mathbf{Q} (\mathbf{I} - \widetilde{\mathbf{S}} \widetilde{\mathbf{S}}^T) \mathbf{Q}^T\right) + (N - \operatorname{rank}(\mathbf{Q})) \cdot \widetilde{\mathbf{s}}_1^T \mathbf{Q}^T \mathbf{A} \mathbf{Q} \widetilde{\mathbf{s}}_1 \\ &= \operatorname{tr}(\mathbf{H}) - \operatorname{tr}\left(\widetilde{\mathbf{S}}^T \mathbf{H} \widetilde{\mathbf{S}}\right) + (N - \operatorname{rank}(\mathbf{Q})) \cdot \widetilde{\mathbf{s}}_1^T \mathbf{H} \widetilde{\mathbf{s}}_1 \\ &= \operatorname{tr}(\mathbf{H}) - \widetilde{\mathbf{s}}_2^T \mathbf{H} \widetilde{\mathbf{s}}_2 + (N - \operatorname{rank}(\mathbf{Q}) - 1) \cdot \widetilde{\mathbf{s}}_1^T \mathbf{H} \widetilde{\mathbf{s}}_1. \end{split}$$

The end result is presented as Algorithm 4.1, where the outer loop averages the result over multiple random rotations  $\Omega \mapsto \Omega U$ . As with XTrace, the loops can be eliminated through vectorization, unless the samples are being computed iteratively via Givens rotations or Householder reflections as mentioned in subsection 3.2. In the latter case, only the inner loop can be eliminated.

5. Numerical experiments. This section presents a comparison of the estimators XTrace and XTraceFull (both with and without resampling) on a variety of synthetic examples. In all cases we fix the matrix dimension N=1000, sample  $\Omega$ 

### Algorithm 4.1 XTrace-Full: Efficient implementation

```
Input: Matrix \mathbf{A} \in \mathbb{R}^{N \times N}; number of test vectors m, resampling number k

Output: Approximation to \operatorname{tr}(\mathbf{A})

1: Sample \mathbf{\Omega} \in \mathbb{R}^{N \times m} with i.i.d. \mathcal{N}(0,1) entries

2: Compute an orthonormal basis \mathbf{Q}_0 for \mathbf{\Omega}

3: QR factorization [\mathbf{Q}_0, \mathbf{A}\mathbf{Q}_0] = \mathbf{Q}\mathbf{R} {See (4.1)}

4: \mathbf{H} = \mathbf{Q}^T \mathbf{A} \mathbf{Q} {Entries overlap with \mathbf{R}}

5: for j = 1, 2, \dots, k do

6: Sample random orthogonal \mathbf{U} \in \mathbb{R}^{m \times m} {\mathcal{O}(m^3) operations}

7: for i = 1, 2, \dots, m do

8: \mathbf{u} = \mathbf{U}\mathbf{e}_i
```

8:  $\mathbf{u} = \mathbf{U}\mathbf{e}_i$ 9: Compute  $\mathbf{S} = \mathbf{R}^{-T}(\mathbf{I}_2 \otimes \mathbf{u})$  { $\mathcal{O}(m^2)$  operations} 10: QL factorization  $\mathbf{S} = \widetilde{\mathbf{S}}\mathbf{L}$  { $\mathcal{O}(m)$  operations} 11:  $\hat{\mathbf{tr}}_{ij} = \operatorname{tr}(\mathbf{H}) - \tilde{\mathbf{s}}_2^T \mathbf{H} \tilde{\mathbf{s}}_2 + (N - \operatorname{rank}(\mathbf{Q}) - 1) \cdot \tilde{\mathbf{s}}_1^T \mathbf{H} \tilde{\mathbf{s}}_1$  { $\mathcal{O}(m^2)$  operations}

12: end for13: end for

14: **return**  $\frac{1}{mk} \sum_{j=1}^{k} \sum_{i=1}^{m} \widehat{\operatorname{tr}}_{ij}$ 

with i.i.d.  $\mathcal{N}(0,1)$  entries, and report the root-mean-squared relative error over 1000 trials. For each trial, each estimator will use the same set of test vectors  $\Omega$ . The variant of XTraceFull with resampling will right-multiply  $\Omega$  by 25 randomly sampled orthogonal matrices, the first of which will always be the identity matrix. Code for XTraceFull is given in listing 1, and the experiments were run using Octave 6.2.0.

We use diagonal matrices with six choices for the eigenvalues  $\lambda$ :

```
 \begin{split} \bullet & \text{ flat: } \lambda = (3-2(i-1)/(N-1): i=1,2,\ldots,N); \\ \bullet & \text{ poly: } \lambda = (i^{-2}: i=1,2,\ldots,N); \\ \bullet & \text{ inv-poly: } \lambda = (2-i^{-2}: i=1,2,\ldots,N); \\ \bullet & \text{ exp: } \lambda = (0.7^i: i=0,1,\ldots,N-1); \\ \bullet & \text{ step: } \lambda = \underbrace{(1,\ldots,1,10^{-3},\ldots,10^{-3})}_{N-50 \text{ times}}; \\ \bullet & \text{ step-decay: } \lambda = \underbrace{(1,\ldots,1,51^{-2},\ldots,N^{-2})}_{50 \text{ times}}. \end{split}
```

Results are presented in Figure 5.1. For four of the six examples, the results are largely the same for all three methods. For the other two, inv-poly and step, XTraceFull performs significantly better than XTrace. In the first case, it is because the outlying eigenvalues are the ones closer to zero, which the Krylov space  $[\Omega, A\Omega]$  can detect significantly better than the space  $A\Omega$  can. The second case is due to the lagging eigenvalues being precisely equal to one another, in which case a sufficiently large Krylov space captures the leading eigenvalues perfectly. When the lagging values are modified to decay slowly (example step-decay), the difference between the methods vanishes.

Figure 5.2 presents a closer view of the effect of resampling  $\Omega U$  for random orthogonal matrices U. In both cases shown, poly and exp, the benefit of resampling is small but nonzero. For the case poly in particular, the benefit appears when the number of test vectors m is very small, but diminishes as m increases.

6. Conclusion and future work. We have proposed two changes to XTrace that will reduce its variance without adding bias or requiring any additional matrix-vector products. In practice, the benefits are minor except for matrices with certain distributions of eigenvalues.

The techniques outlined in section 4 could potentially be extended to cases where we deflate vectors over a larger Krylov space  $[\Omega, \mathbf{A}\Omega, \dots, \mathbf{A}^{q-1}\Omega]$ . This can be useful in cases where we want to estimate the trace of  $f(\mathbf{A})$  and matvecs with  $f(\mathbf{A})$  are approximated by matrix polynomials, e.g., representing the number of triangles in a graph as  $\operatorname{tr}(\mathbf{A}^3)$ .
