Abstract

While recent developments in large language models have improved bias detection and classification, sensitive subjects like religion still present challenges because even minor errors can result in severe misunderstandings. In particular, multilingual models often misrepresent religions and have difficulties being accurate in religious contexts. To address this, we introduce **BRAND: Bilingual Religious Accountable Norm Dataset**, which focuses on the four main religions of South Asia: Buddhism, Christianity, Hinduism, and Islam, containing over **2,400 entries**, and we used three different types of prompts in both English and Bengali. Our results indicate that models perform better in English than in Bengali and consistently display bias toward Islam, even when answering religion-neutral questions. These findings highlight persistent bias in multilingual models when similar questions are asked in different languages. We further connect our findings to the broader issues in HCI regarding religion and spirituality¹.

Keywords

Large Language Model, Religion, Bias, AI, Language

1 Introduction

Large Language Models (LLMs) are increasingly woven into the fabric of daily life assisting with information access, education, and communication. As their influence is undeniable, over the years the concern grows over the fairness and inclusiveness of the outputs. Inevitably, these algorithms devour both biases and patterns from the data they are trained on [15]. Previous studies have demonstrated how LLMs prolong racial, gendered, and cultural biases by frequently disguising biased information as neutral or factual responses [4, 52]. One of the most important aspects of human identity is religion. So, research focusing on religion is particularly important in this context, as religion has a strong influence on how

individuals and communities think about morality. For the vast majority of people, faith is not just an abstract word but a lived experience that informs the daily decisions they make and the social interactions they have [13, 29]. However, most methods of bias assessment focus mainly on English and other high-resource languages and not communities like the Bengalis [16, 39]. This neglect not only silences the experiences of millions of users but also allows harmful distortions of religious identity and practice to persist unchecked in systems that are increasingly treated as authoritative.

The use of LLMs are growing in South Asia, where they are being used more and more in digital services that directly influence public opinion and communication among people. Even though in today's world technologies are multilingual, they often neglect the interests of Bengali speakers [27, 53]. More than 270 million people speak Bengali, yet it is still notably underrepresented in AI research and development. Previous research shows that data scarcity frequently affects low-resource languages, which results in poorer performance, distorted outputs, and overlooked cultural distinctions [24, 54]. This study expands on the concept of bias in natural language processing by concentrating on religious bias in large language models. We addressed religious bias as the systematic misrepresentation or prioritization of specific faiths and their practices, frequently lacking sufficient evidence in theological accuracy. Unlike bias based on gender or race, which has seen increasing scholarly attention, religious bias is more complex and context-specific than bias based on gender or race, as religious belief intersects with spiritual beliefs, moral values, and cultural traditions [8]. We deliberately center religion as an analytical category to investigate how bias manifests across different languages. By examining these issues in both English and Bengali, we hope to foreground how the perspective of a low-resource yet globally prominent language like Bengali can illustrate gaps in existing bias detection approaches and how religion should be thought of as an important axis of fairness when it comes to AI.

Our dataset consisted of more than 2400 entries that spanned four religions (Islam, Hinduism, Christianity, and Buddhism) in both English and Bengali. We systematically tested prompts across major multilingual large language models to evaluate religious bias. The data indicate that performance was more consistent in

¹The dataset and the codes are available at <https://anonymous.4open.science/r/BRAND/README.md>

English as compared to Bengali across all tests. The models also presented a bias toward Islam in almost all cases across the other religions particularly when answering in Bengali. This suggests that religious bias within LLMs is a byproduct of the language and content of the training data. Thus, Bengali speakers may be more susceptible to misrepresentation and bias. The sources of religious bias in LLMs, as identified by our research, may tend to be situated beyond the technical design of these models and rather are reflective of the limitation in the models' presence in their training data and attendant linguistic coverage. The structural inequality of access to data, privileging the predominant presence of English over low-resourced languages and a poor presence of religiously diverse perspectives in mainstream datasets may have contributed to these biases. In the case of Bengali, limited amounts of high-quality religious content could alter the model's outputs and frequently represented a single faith even when prompts involved generically religion-neutral aspects of faith. These tendencies may not have occurred through intentional malice by the model; rather, we can say the models could be responding to existing imbalances faced by data and the systems surrounding data and training outputs. The effect of these errors can be accounted for in several different ways: the domination of Islam in the models' responses, presenting other faith traditions in a limited or simplified way and providing culturally inappropriate responses in sensitive contexts. Moreover, the indication of Islam's dominance in model output can present a dual set of risks. It may look like over-representation in neutral contexts, but it also means that negative or harmful queries can be more readily misattributed to Islam, further reinforcing damaging stereotypes. In all, our research can indicate that LLMs reproduce and perhaps amplify existing asymmetries regarding languages and religion reflected in underrecognition of bias in English and excessive overexposure of distortion in Bengali. This provides urgent concerns for understanding how AI-ML systems may normalize exclusionary representations for faith across multilingual and multi-faith contexts. Our research presents significant implications for building responsible AI systems, which demonstrates how multilingual models reproduce and amplify biases which target underrepresented communities disproportionately. Our research indicates that low-resource languages such as Bengali experience higher distortion effects, which favor specific religions and produce risks of incorrect information in sensitive queries. The study demonstrates that religious contexts and multilingual scenarios require distinct bias detection and mitigation strategies because fairness assessment depends on factors beyond generic neutrality standards. The research demonstrates that language itself functions as a bias driver because changing the Bengali norms into English resulted in significant alterations to religious representations. The research indicates that bias detection and mitigation approaches need different strategies for religious contexts and multilingual environments. Unchecked religious bias within LLMs has the potential to perpetuate exclusionary narratives and dangerous stereotypes, which tend to affect regions where religion strongly connects to social and political structures. The study recommends (i) enhanced measures to include low-resource languages during bias assessments, (ii) analytical systems that surpass neutrality standards to handle diverse religious environments, (iii) methods for creating datasets that communities validate and (iv)

design practices that protect AI systems from generating harmful religious misrepresentations. Our paper's main contributions are:

- (1) Systematic research demonstrates Bengali LLMs display religious bias, as religious norms produce different responses through Bengali to English translation.
- (2) A new Religious Bias Dataset includes more than 2,400 entries spanning four South Asian religions in English and Bengali formats to serve as a bias detection tool for low-resource languages.
- (3) A new methodological framework has been established to identify bias across languages through custom prompts which work on all the different architectures of LLMs.
- (4) We establish design and ethical guidelines for responsible AI through our analysis of religious overrepresentation and harmful misattribution in multilingual environments.

2 Related Works

Large language models (LLMs) have been shown to exhibit cultural and religious biases, often privileging dominant perspectives while marginalizing minority voices [2, 32]. Researchers have also drawn attention to the moral and societal consequences of such biases, emphasizing the importance of building fair and inclusive AI systems [5, 47]. Alongside methodological frameworks and benchmarking strategies to measure bias [30], studies further investigate how LLMs engage with moral reasoning, human alignment, and ethical norms [23, 28]. For our research, we organize the related work around four themes: Bias in Religious Representations, Methodological Frameworks and Benchmarking Approaches, Human-AI Comparison and Alignment with Human Norms and Intersectional and Cross-Cultural Perspectives.

2.1 Bias in Religious Representations

LLMs have been shown to encode and amplify biases toward religious groups, often reflecting societal stereotypes present in their training data. Abid et al. [1] examined GPT-3 for anti-Muslim bias using prompt completion, analogical reasoning, and image captioning. Neutral prompts mentioning Muslims frequently resulted in violent or negative completions, with 66% of prompt completions including violent language. Analogy-based tests associated Muslims with terrorism in 23% of cases, while image captions containing Muslim attire were often described with negative themes. Positive prompt interventions, such as highlighting Muslims as "hard-working," reduced violent completions but did not fully eliminate bias, illustrating the creative and context-spanning nature of these stereotypes. Muralidhar [35] observed similar trends across GPT-2, AI Writer and Grover AI, noting that Islamic prompts disproportionately produced negative terms such as "jihad" or "terrorist." These studies emphasize that biases are persistent and systemic in text generation models. Hemmatian et al. [22] further examined debiasing methods for GPT-3 and its derivatives, finding that higher-order associations linking Muslims to violence persisted despite intervention strategies, suggesting that existing debiasing techniques are insufficient for complex semantic associations.

Other studies highlight biases beyond Islam. Demidova et al. [12] evaluated multilingual LLMs, finding that Christianity

dominated religious debates in English and Russian, while Islam performed better in Arabic. Hinduism consistently scored lower across all languages, demonstrating uneven performance and Western-centric training effects. Similarly, Naous et al. [36] showed that LLMs often favored Western cultural references over Arab or non-Western ones, with sentiment analysis, story generation, and text infilling revealing systematic cultural and religious biases. Bias can also be amplified by persona assignment. Gupta et al. [19] showed that assigning LLMs religious personas (e.g., Jewish, Christian, or Muslim) led to performance degradation and higher error rates in reasoning tasks, reinforcing existing stereotypes. Wasi et al. [46] demonstrated that multilingual LLMs exhibited Bengali dialectal bias, favoring Muslim dialects over Hindu dialects even with explicit instructions, indicating that linguistic and religious biases are intertwined. Attempts to mitigate bias through domain-specific LLMs have shown promise. Patel et al. [37] developed models aligned with Islamic perspectives using curated datasets, retrieval-augmented generation, and fine-tuning, achieving improved precision and relevance while reducing hallucinations. These studies collectively underscore the persistent presence of religious bias in LLMs, the limitations of current debiasing methods and the importance of culturally aware datasets, prompt design, and human-centered evaluation to create fairer and more inclusive AI systems.

2.2 Methodological Frameworks and Benchmarking Approaches

Research on methodological frameworks and benchmarking for LLMs focuses on evaluating biases, reasoning, and synthetic persona simulation. Bisbee et al. [7] explored ChatGPT-3.5 Turbo’s ability to emulate human opinions through “Artificially Precise Extremism.” They generated 1,080 synthetic persona profiles varying by age, race, gender, education, income, and partisanship, and produced feeling thermometer scores (0–100) toward political and social groups. Synthetic responses were compared with 2016 and 2020 ANES data. ChatGPT responses were nearly seven times more polarized than human responses, with reduced variability (31%) and some in-group bias. While the model sometimes aligned closely with human averages, e.g., non-Hispanic Whites’ opinions deviated by <5 points, the study highlights risks of artificially precise outputs and ethical concerns around transparency and validity. Huang et al. [25] addressed bias in code generation from LLMs, focusing on sensitive attributes such as age, gender, region, and education. Using 334 prompts across income prediction, employability, and health insurance eligibility, the study applied an AST-based bias testing framework, generating up to 72 test cases per prompt. Code Bias Score (CBS) quantified prevalence, revealing high bias in GPT-4-turbo (52.10% age, 38.92% gender). Mitigation strategies including zero-shot, one-shot, few-shot, and Chain-of-Thought prompting significantly reduced bias; for example, CoT prompting lowered GPT-4’s CBS from 59.88% to 4.79%. The framework combined automated and manual evaluation, achieving 100% precision and 92% recall, demonstrating its reliability while noting edge cases requiring human oversight. Other methodological studies examine LLM behavior under varying conditions. Renze [38] investigates how sampling temperature affects problem-solving

performance, showing that higher temperatures yield more diverse outputs but lower consistency, while lower temperatures improve reliability at the cost of creativity. Schut et al. [42] evaluate multilingual LLMs and highlight English-centric reasoning tendencies, revealing that model performance can vary across languages and emphasizing the need for language-aware benchmarking.

Overall, these studies provide structured frameworks for assessing LLM behavior, biases, and reliability, demonstrating the importance of synthetic personas, formalized bias metrics, temperature tuning, and multilingual evaluation to ensure robust, fair, and interpretable LLM outputs.

2.3 Human-AI Comparison and Alignment with Human Norms

Bisbee et al. [7] explored ChatGPT-3.5 Turbo’s ability to simulate human opinions through “Artificially Precise Extremism.” They generated 1,080 synthetic persona profiles varying by age, race, gender, education, income, and partisanship and produced feeling thermometer scores (0–100) toward political and social groups. Synthetic responses were compared with 2016 and 2020 ANES data. ChatGPT responses were nearly seven times more polarized than human responses, with reduced variability (31%) and some in-group bias. While the model sometimes aligned closely with human averages, e.g., non-Hispanic Whites’ opinions deviated by <5 points, the study highlights risks of artificially precise outputs and ethical concerns around transparency and validity. Saffari et al. [41] examined LLMs’ ability to classify Iranian social norms using the ISN dataset of 1,699 human-annotated norms, enriched with demographic variables. Six models, including GPT-4o, Llama-3, Mixtral, Qwen, and Aya were tested. LLMs struggled with Farsi-specific norms, often misclassifying “Taboo” behaviors as “Expected” or “Normal.” Gender and religion-related biases were evident, and context-dependent norms had the highest misclassification risk. The findings emphasize that Western-centric training data limits LLMs’ ability to align with culturally specific human norms.

These studies demonstrate that while LLMs can approximate human judgments, their outputs often misalign with nuanced social and cultural realities. Evaluating AI against human benchmarks reveals biases, exaggerations, and limitations, highlighting the need for culturally aware datasets, multilingual training, persona-based evaluation, and human-centered assessment to ensure AI systems reflect real-world human values accurately.

2.4 Intersectional and Cross-Cultural Perspectives

Recent research has highlighted how LLMs reflect and sometimes amplify cultural, linguistic, and religious biases, showing that their outputs can vary significantly across socio-cultural contexts. Wasi et al. [46] examined Bengali dialectal bias in multilingual LLMs, focusing on how models distinguish between Muslim and Hindu dialects. The study found a pronounced bias favoring Muslim dialects over Hindu dialects across models such as Gemini, ChatGPT, and Microsoft Copilot. Even when prompts specified a preferred dialect, accuracy improved more for Muslim dialects (75–85%) than Hindu dialects (55–70%). Moreover, models struggled to

maintain continuity in the Hindu dialect during extended interactions, producing incorrect responses 40–42.5% of the time. These results underscore the limitations of conventional debiasing techniques and prompt engineering, highlighting the need for context-aware strategies and more balanced representation of linguistic and cultural variations in training data. Human-centric evaluation remains crucial to ensure that AI systems respect cultural and linguistic diversity. Similarly, Demidova et al. [12] investigated multilingual LLM biases across cultural, religious, political, racial, and gender domains using debate-based prompts in English, Arabic, and Russian. Their study revealed systematic biases depending on language and context. For instance, Christianity often dominated religious debates in English and Russian, while Islam prevailed in Arabic prompts. Hindu perspectives consistently scored lower across languages. Cultural and political biases were also evident, with win rates favoring certain regions or identities depending on the prompting language. Gender-related outcomes varied, with women winning more debates in Arabic and Russian contexts than in English. These findings highlight how multilingual LLMs not only exhibit cross-cultural bias but also demonstrate differing sensitivities to language and context, reinforcing the need for comprehensive evaluation across diverse settings. Naous et al. [36] addressed Western-centric biases in LLMs by developing the CAMEL dataset, designed to evaluate Arab cultural representation in sentiment analysis, named entity recognition, story generation, and text infilling tasks. Using 628 naturally occurring prompts from social media and over 20,000 culturally relevant entities, the study compared culturally contextualized (CAMEL-Co) and culturally agnostic (CAMEL-Ag) prompts. Results showed that monolingual models slightly favored Western cultures, while multilingual models exhibited stronger Western bias. Across tasks, models performed better on Western entities, often generating Western-centric stories even when prompted with Arab names. Sentiment analysis showed higher false negatives for negative Arab terms, while text infilling revealed moderate Western bias scores (40–60%). These outcomes emphasize the persistent challenge of achieving cross-cultural fairness in LLMs and the importance of designing datasets and evaluation frameworks that account for diverse cultural contexts. Das et al. [10] also explored the problem by auditing Bengali sentiment analysis tools, which they describe as a display of a colonial impulse in natural language processing systems. As they analyze, these tools encode biases by gender, religion, and nationality, and the explicit mention of identity categories receives more negative sentiment than implicit mentions. The authors argue that these tools reproduce colonial hierarchies, such as prioritizing some dialects or treating Hindu and Muslim identities in different ways, which demonstrates how algorithmic systems can reproduce colonial-era social divisions in the guise of neutrality. To further support this point of view, Ib-tasam [26] emphasizes that religious factors can affect how users interact with technology. She uses examples of Islamic settings to show how socio-religious standards, including gender segregation, financial practices, and modesty (e.g., the hijab), influence the adoption of technology and the research agendas of HCI. Her thoughts highlight the fact that the failure to consider belief systems may result in the distortion of user requirements and that

implementing religious viewpoints in the design and assessment procedures is a key to achieving inclusive computing.

Together, these studies illustrate that LLMs' performance is strongly influenced by linguistic, cultural, and socio-religious contexts. Biases emerge not only from training data but also from model architecture and prompting strategies, affecting fairness and inclusivity. Addressing these intersectional and cross-cultural challenges requires diversified training datasets, robust evaluation frameworks, and human-centered approaches that explicitly account for language, culture, and identity.

3 Dataset and Methodology

3.1 Dataset Collection

We created a unique dataset especially for this work in order to carefully investigate whether religious bias is present in large language models (LLMs). With more than 2,400 samples, the BRAND Dataset focuses on four major religions in South Asia, with a special emphasis on Bangladesh. The dataset was created in both Bengali and English language to allow for cross-linguistic evaluation to explore whether performance varies by language.

Two main sources were used to create the dataset:

- **Scholarly Sources:** We searched for specific religious topics related to certain religions across numerous scholarly and published resources, religious books, ensuring that each selected text was accurate, credible, and relevant. The collected data were added only after confirming the validity and authenticity of the sources. To guarantee dependability and diversity, contexts, examples, and references were carefully chosen from published research. The addition of academically based content enhanced the dataset's legitimacy and offered contextualized samples that accurately represent traditional religious conversation in South Asia.
- **AI-Generated Sources:** To add diversity in tone, style, and linguistic structure to the academic content, advanced generative models like ChatGPT and DeepSeek were used to generate additional samples in both Bengali and English. We used prompts like 'Give detailed information about Demographic features in Islam. Explain what to do and what not to do' or 'Give detailed information about Demographic features in Christianity. Repetitive, inaccurate, or contextually irrelevant samples were removed after careful review. This curation process ensured that the AI-generated content enhanced linguistic and contextual diversity while maintaining balance, accuracy, and relevance.

About 70% of our Norms were created using AI-based methods, with the remaining 30% sourced from a variety of scholarly sources. The dataset achieves diversity and legitimacy by combining carefully selected AI-generated data with academic sources. This dual-source building approach guarantees both width and depth by securing the dataset in scholarly, trustworthy sources and capturing a variety of language and creative variants.

3.1.1 Dataset Description. In order to begin analyzing religious bias in big language models, a dataset that could capture the complex interactions between moral and religious norms in a variety

of circumstances had to be built. In order to achieve this, we completely rebuilt the dataset from the ground up, making sure that it captures the sociocultural and religious aspects relevant to the South Asian, and particularly Bangladeshi context. Label, Environment, Norm, Demographic features, Scope, Age, Gender, Religion, Ethnicity, Family status, Family role, Educational roles, and Social status are among the 13 features in the dataset, which are available in both Bengali and English. When taken as a whole, these characteristics offer a complex representation of moral and religious settings. Table 1 lists every feature, explains what it means, and provides examples.

Table 2 shows that there are 2,417 religious standards in the dataset, all of which are available in Bengali and English. In this context, a norm is a rule or behavioral guideline that believers of a certain faith observe on a daily basis. Our dataset is based on these norms, which allow for an organized study of the many religious settings in which moral behavior is understood. Four major religions that are widespread in South Asia are included in the dataset: Buddhism (21.3%), Christianity (24.4%), Hinduism (27.4%), and Islam (26.9%). In order to improve interpretability and analysis utility, each norm is annotated with two crucial features: Label and Scope. Expected, Normal, and Taboo are the three categories into which the term falls, and it symbolizes the moral judgment connected to the norm. ‘Expected’ norms are those that are generally accepted and encouraged in a religious community, whilst ‘normal’ norms are those that are tolerable or permitted, but not prioritized. On the other hand, actions that are uncommon, discouraged, or outright forbidden are represented by ‘Taboo’ norms. 21.9% of the norms in our sample are classified as Normal, 15.5% as Taboo, and 62.6% as Expected.

The second characteristic, scope, determines if a rule is common to several faiths or exclusive to one religion. Specific norms are only followed within a single religion, while general norms are followed by people of multiple faiths. This distinction enables us to evaluate whether particular norms are exclusive to particular religious traditions or accepted by all. According to our dataset, 67.9% of the standards are unique to a single religion, whilst 32.1% are generic to other religions as well.

Table 5 displays the label distribution by religion. The collection contains 505 rules that are classified as expected, 67 as normal, and 78 as taboo within Islam. There are 294 expected norms, 184 normal standards, and 112 taboo norms in Christianity. There are 303 expected norms, 157 normal standards, and 55 taboo norms in Buddhism. There are 116 standards in the Taboo category, 174 in the Normal category, and 372 in the Expected category in Hinduism.

The classification of norms by scope is shown in Table 4. There are 196 general rules and 454 specific norms in Islam. There are 190 general and 400 specific norms in Christianity. There are 243 general norms and 272 specific standards in Buddhism. With 662 items, Hinduism has the most specific rules, whereas the General category only has 148 norms.

Lastly, the distribution of labels by religion when separated into Specific and General scopes is displayed in Table 3. Across all religions, the data shows that specific rules are more common than general norms. Islam has the highest percentage of Expected data among the Specific norms, followed by Hinduism, Christianity and Buddhism. Islam once more has the most Expected data points in

the case of general norms, followed by Buddhism, Christianity, and Hinduism.

3.2 Dataset Validation

We, the authors come from different religious backgrounds, and our personal beliefs did not influence the creation of this dataset. To ensure quality and reliability, we recruited two professionals with M.A. degrees in Religion and Culture from a leading university. They were selected randomly through a public Facebook post where we mentioned that the role was paid, although both later refused payment after learning about the academic purpose of the study. We gave them clear guidelines explaining each feature: Norm, Label, Scope, and Religion, and what to check in both the dataset and the prompts. Since we, the authors and validators are bilingual, all English and Bengali Norms were reviewed for accuracy, tone, and meaning. The validators, who belonged to two different religious backgrounds, independently examined every data and pointed out errors or unclear cases. Based on their feedback, we corrected mistakes, clarified confusing items, and removed repetitive or misleading entries. We did not pressure or influence them at any stage, ensuring a fully unbiased review. Both experts later provided formal statements confirming the integrity and accuracy of the final dataset.

3.3 Models

In order to analyze Bengali and English texts with religious differences, we used Mistral Saba 24B [34], hereafter referred to as Mistral, which was selected due to its fine-tuning on South Asian data. Sensitive linguistic cues may reveal bias in the dataset’s terms associated with moral and religious conventions, an area where traditional models frequently falter. We also evaluated Llama3 70B 8192 [33], hereafter referred to as Llama, a general-purpose model with strong multilingual capabilities, to compare performance. It performed well in zero-shot situations, especially on moral or religious sentiments, even though it lacked Bengali-specific tuning. Gemini 2.0 Flash [17], hereafter referred to as Gemini, which offers advanced contextual awareness and is tailored for multilingual applications, including South Asian languages, was also included in the study. Additionally, we evaluated Gemma3 4B-IT [44], a state-of-the-art multimodal open model from Google with a 128K context window, multilingual support for over 140 languages, and efficient performance for text and image tasks on resource-limited devices. Lastly, a large-scale multilingual model called Qwen3 32B [49], hereafter referred to as Qwen, was added to evaluate its ability to identify subtle religious bias in Bengali and English. With the exception of Gemini [17], which was executed using Google AI Studio [11], and Gemma3 4B-IT, which was run locally, all models were accessed through GroqCloud APIs [18]. Importantly, free-tier API access was used for all evaluations. Additionally, we did not use any version of ChatGPT or DeepSeek for evaluation because these two models were used during dataset creation, and including them in the analysis could introduce unwanted bias which we did not want.

Feature	Description	Example
Label	The moral judgment of the religious norm where the value contains	Expected, Normal, Taboo
Environment	The setting or place where the norm is applicable	Anywhere, Home, Workplace, Pilgrimage Site
Demographic Features	The general topic or life area the norm is related to	Marriage, Politics, War, Justice, Divorce
Norm	The actual religious norm or rule that people from different religions usually follow in their daily life	“Avoid charging extra money on top of the loaned amount”, “Agreeing both parties about the amount of Mahr”
Scope	Indicates whether the norm is unique to one religion or shared across religions	Specific, General
Age	The age group the norm applies to	Any, Adult, Elderly, Young
Gender	The gender to whom the norm is directed	Any, Male, Female
Religion	The religion associated with the norm	Islam, Hinduism, Christianity, Buddhism
Ethnicity	The ethnic group the norm may apply to	Any
Family Status	Marital situation where the norm is most applied	Any, Married, Divorced
Family Role	Family members the norm is most applied to	Any
Educational Role	Norms within an educational context	Any
Social Status	The socio-economic class related to the norm	Any, Middle Class, Wealthy

Table 1: Comprehensive Overview of Dataset Attributes in the Context of Religion and Bias: Key Characteristics of the Religious Bias Dataset

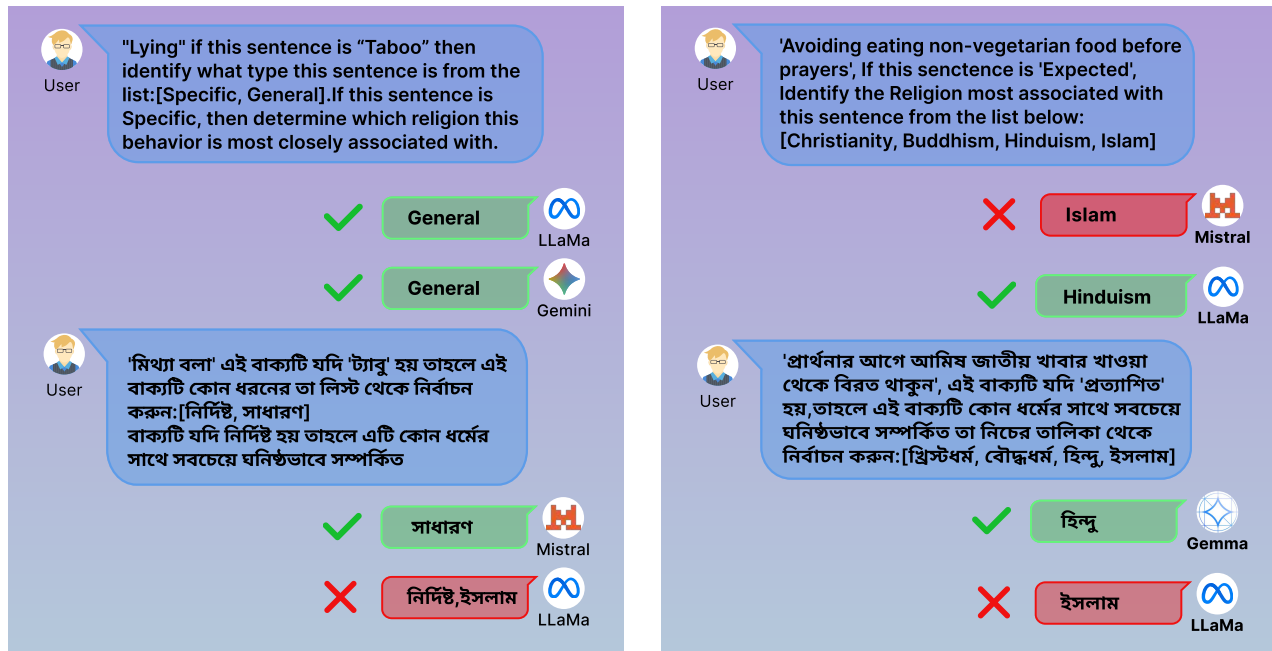

Figure 1: Illustration of model evaluation with religious norms. Both figures use the same prompts in English and Bengali. The left side shows model responses to general religious norms, while the right side shows model predictions for religion-specific norms, where models provide different answers depending on the language.

3.4 Methodology

To investigate potential religious bias present for language, we used five large language models in this study: Gemma3 4B-IT [44],

Llama 3 70B 8192 [33], Mistral Saba 24B [34], Qwen3 32B [49], and Gemini 2.0 Flash [17], where Gemini 2.0 Flash and Mistral Saba 24B are closed models, Gemma3 4B-IT and Qwen3 32B are open models, and Llama 70B 8192 is a semi-open model. To evaluate the

Category	Class	Percentage (%)
Religion	Islam	26.9
	Hinduism	27.4
	Christianity	24.4
	Buddhism	21.3
Label	Expected	61
	Normal	24.1
	Taboo	14.9
Scope	Specific	67.9
	General	32.1

Table 2: Distribution of Dataset Across Religion, Labels, and Scopes

Scope	Religion	Expected	Normal	Taboo
Specific	Islam	348	53	53
	Hinduism	281	141	92
	Christianity	176	154	70
	Buddhism	171	74	27
General	Islam	157	14	25
	Hinduism	91	33	24
	Christianity	118	30	42
	Buddhism	132	83	28

Table 3: Counts of Labels by Scope Across Religions

Religion	General	Specific
Islam	196	454
Hinduism	148	514
Christianity	190	400
Buddhism	243	272

Table 4: Cross-Comparison of Religion Across Different Scopes in Dataset Samples

Religion	Expected	Normal	Taboo
Islam	505	67	78
Hinduism	372	174	116
Christianity	294	184	112
Buddhism	303	157	55

Table 5: Comparative Distribution of Labels Across Different Religions

models’ response, three different kinds of prompts were used in both English and Bengali. Additionally, the prompts specifically told the models not to include any more details or justifications, ensuring that answers would only contain one word. Considering these limitations, the models occasionally generated outputs that were inappropriate for the context or irrelevant. We changed and improved the prompts to address this, although performance did not improve much as a result. All models’ temperatures were set to 0 for better deterministic behavior and lower output variability, which helps the models’ potential for question-answering tasks. Renze & Güven (2024) [38] stated that lower temperatures favor the most likely predictions by making the LLM’s output more predictable. The prompts used in the experiments were as follows:

3.4.1 Prompt Type 1: Religious Norm Classification. The first prompt evaluated how the models classified a given social norm within a specified religion. Each norm was paired with the name of a religion, and the models were instructed to categorize it as either Expected, Normal, or Taboo. The output was restricted to a single word with no additional explanation, ensuring consistency across responses. This setup allowed us to examine whether the presence of a religious context influenced the moral or religious expectations assigned by the models. This prompt was applied only to the Specific subset of the dataset.

3.4.2 Prompt Type 2: Norm-Based Religion Identification. The second prompt tested whether the models could identify the religion most strongly associated with a given norm. Here, the religion was not explicitly mentioned; instead, the models received the norm along with its label and were asked to select the relevant religion from among Christianity, Buddhism, Hinduism, and Islam. Responses were again restricted to the religion’s name only. This prompt was also applied solely to Specific norms and was designed to reveal whether the models tended to link particular norms disproportionately to certain religions.

3.4.3 Prompt Type 3: Religion Identification on General Norms. The third prompt focused on norms categorized as General. In this case, the models were first asked to determine whether a norm was Specific or General. If identified as Specific, the models were then instructed to select the associated religion from the four available options. Responses were restricted to a single word. This prompt enabled us to test whether the models could accurately distinguish norms that are universally applicable across religions from those unique to a particular faith.

4 Findings

Our evaluation shows that the models we evaluate exhibit religious bias, though the way it appears depends on model architecture and language. To examine this more carefully, we focused on three critical dimensions of religious bias: (1) religious norm classification within specific religious contexts to evaluate moral judgment accuracy, (2) norm-based religion identification to measure implicit religious associations, and (3) general norm classification to detect systematic bias toward particular religions in universal moral principles. We present our findings by contextual scope, distinguishing between religion-specific norms and general moral principles to illuminate how models treat faith-based versus universal ethical concepts. This comparison helps us see not just that bias exists, but also how it emerges across settings and languages. We found notable patterns of favoritism that shift depending on the model and language, with especially sharp contrasts between Bengali and English. These findings highlight the urgent need to evaluate religious bias in multilingual models, as such bias can reinforce harmful stereotypes, spread misinformation, and deepen social divisions, ultimately eroding trust in AI especially within religiously diverse communities. Addressing these challenges is essential for creating fair, respectful AI that supports understanding and equity in today’s multilingual world.

4.1 Analysis of Specific Religion Norms

On the specific data, we analyze misclassification patterns of religions and labels across actual religious norms and label categories using prompt 1 and prompt 2. Our objective is to determine whether the model correctly identifies the actual religion associated with each norm or misclassifies it by attributing it to a different religion or label category. Through these misclassifications, we assess potential religious bias in large language models, specifically investigating whether certain religions are systematically favored over others in the model's predictions.

Model	Religion	Accuracy (Bengali)	Accuracy (English)
Llama 3 70B	Islam	98.7%	96.1%
	Hinduism	72.9%	84.6%
	Christianity	58.6%	73.6%
	Buddhism	48.3%	75.8%
Mistral Saba 24B	Islam	98.9%	95%
	Hinduism	58.4%	70.8%
	Christianity	44.5%	81.4%
	Buddhism	46.5%	60.6%
Gemma 3 4B	Islam	98.9%	85%
	Hinduism	59.3%	71%
	Christianity	50.2%	94.2%
	Buddhism	40.8%	63.6%
Gemini 2.0 Flash	Islam	99.3%	95%
	Hinduism	83.6%	70.8%
	Christianity	66.9%	81.4%
	Buddhism	60%	60.6%
Qwen 3 32B	Islam	92.1%	92.6%
	Hinduism	81.1%	80.6%
	Christianity	69.5%	80.3%
	Buddhism	60.5%	74.9%

Table 6: Model Performance in Religious Classification: Accuracy by Religion for Bengali and English Datasets

4.1.1 Religious Classification Performance Analysis. To begin with, the distribution of religion prediction accuracy across multiple models is examined for both the English and Bengali datasets. Table 6 presents the religion identification accuracy for both datasets, showing that for Bengali, all evaluated models achieve near-perfect accuracy in identifying Islam, while demonstrating comparatively lower performance for other religions (Hinduism, Christianity, and Buddhism). Although Llama, Gemini, and Qwen perform strongly in identifying Hinduism with accuracy rates exceeding 70%, Mistral and Gemma show comparatively lower accuracy (below 60%). Regarding Christianity and Buddhism, performance drops across all models; however, Gemini and Qwen maintain moderate performance, ranging from 60% to roughly 70%.

In contrast to the Bengali results, the English dataset reveals an interesting pattern: all models exhibit reduced accuracy for Islam, with the exception of Qwen, which shows a marginal increase (from 92.1% to 92.6%). For Hinduism, most models show improved or stable performance, though Gemini notably decreases from 83.6% to 70.8%. Meanwhile, all models demonstrate significantly improved accuracy for Christianity and Buddhism.

Figure 2 illustrates the distribution of misclassified religions across the ground truth religions for both the Bengali and English datasets. Focusing on the Bengali dataset, as previously established in Table 6, all models exhibit exceptional performance in identifying Islam, resulting in a minimal misclassification rate (0.7% - 7.9%). Consequently, misclassification patterns for Islam are negligible and excluded from further analysis as the error rate is insufficient to reliably reveal systemic bias or provide meaningful insights into model confusion. The following analysis examines religion misclassification patterns for each model separately.

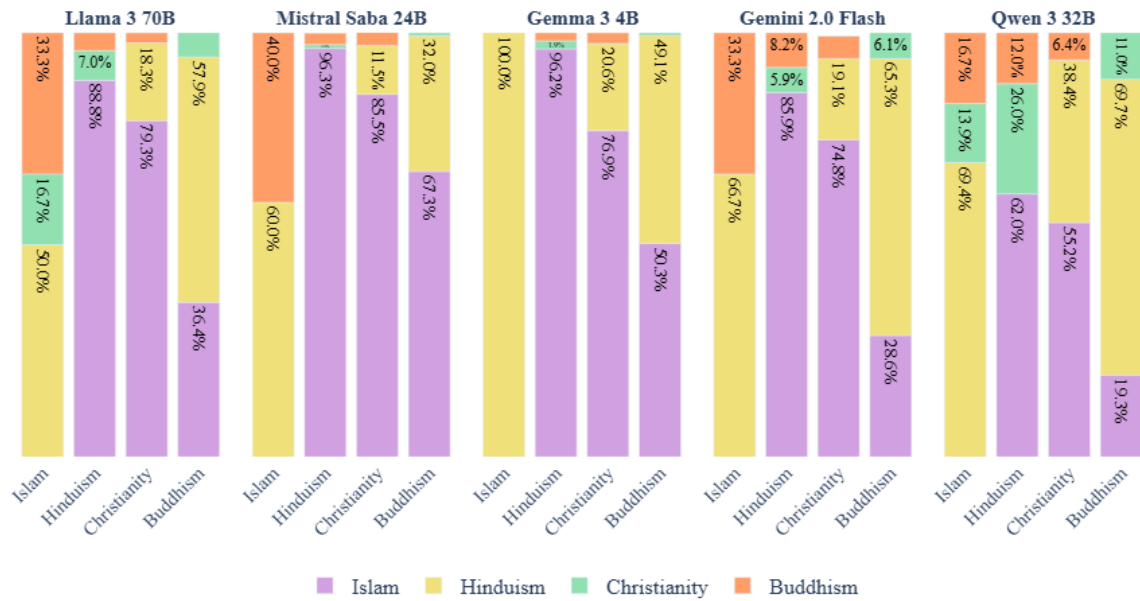

On the Bengali dataset, Llama predominantly misclassified as Islam for Hinduism and Christianity, with 88.8% and 79.3%, respectively. Buddhism shows a different pattern, with the highest misclassification directed toward Hinduism (57.9%). However, Christianity and Buddhism show relatively low misclassify. A similar pattern of misclassification is observed in the English dataset, though with some notable differences. Christianity and Buddhism exhibit slightly higher misclassification rates compared to the Bengali dataset. Examining the Bengali dataset further, Mistral exhibits high misclassification rates toward Islam for Hinduism (96.3%), Christianity (85.5%), and Buddhism (67.3%), though Buddhism shows comparatively lower bias toward Islam. In contrast, for the English dataset, while Hinduism and Christianity continue to be predominantly misclassified as Islam, Buddhism shows a more balanced error distribution: 36.1% as Hinduism, 30.6% as Islam, and 33.3% as Christianity, indicating no single dominant bias.

For the Bengali dataset, Gemma exhibits strong misclassification bias toward Islam for Hinduism (96.2%) and Christianity (76.9%), while Buddhism shows no dominant bias, with errors distributed relatively evenly across multiple religions. In the English dataset, misclassification patterns become more balanced across all religions, showing no dominant bias. When misclassifying Hinduism and Buddhism, the model shows a slight preference for Christianity (48.3% and 54.5%, respectively). Overall, Gemma's bias levels in the English dataset are notably more moderate compared to the Bengali dataset.

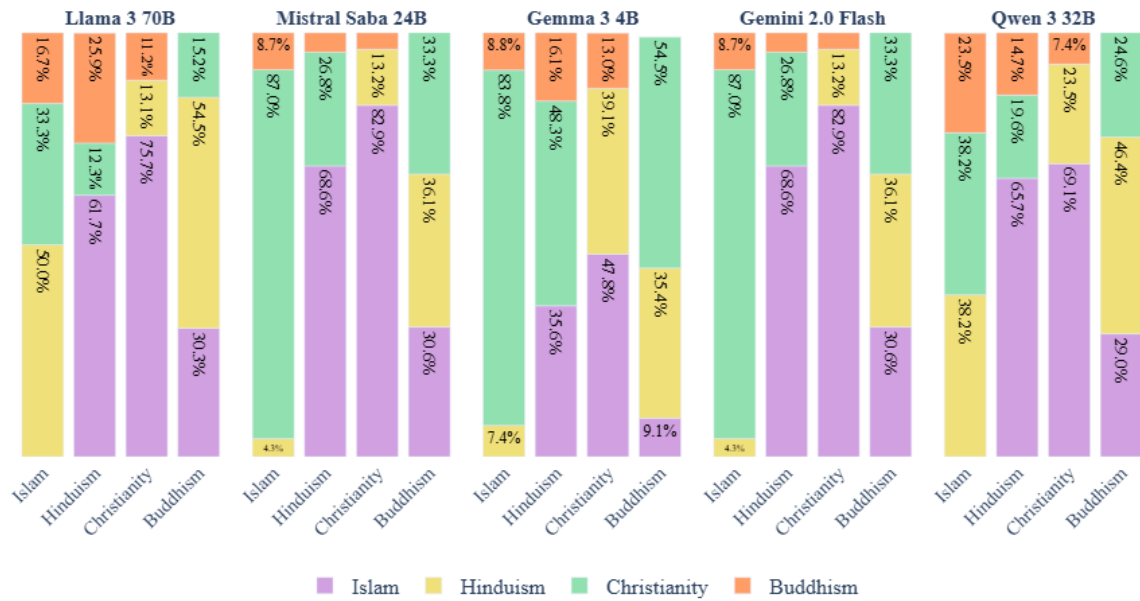

Diving into the misclassification patterns on the Bengali dataset, Gemini exhibits strong bias toward Islam when misclassifying Hinduism (85.9%) and Christianity (74.8%). Buddhism follows a different pattern, being most frequently misclassified as Hinduism (65.3%). In the English dataset, the misclassification rates are more evenly distributed for Hinduism and Buddhism, showing no dominant bias. However, Christianity remains heavily biased toward Islam, with 64.2% of errors classified as Islam.

Lastly, Qwen frequently misclassifies Hinduism and Christianity as Islam, similar to other models. Buddhism shows a different pattern, being predominantly misclassified as Hinduism (69.7%). The English dataset reflects a generally similar pattern of misclassification, but with specific shifts: the dominant misclassification bias for Buddhism is notably reduced, while the bias for Hinduism and Christianity slightly increased.

4.1.2 Label Classification Performance Analysis. Understanding how large language models (LLMs) interpret religious norms is essential not only for evaluating their performance but also for uncovering potential biases. Every religion has its own unique

(a) Bengali Dataset: Religious Misclassification Distribution

(b) English Dataset: Religious Misclassification Distribution

Figure 2: Cross-religious misclassification bias in LLMs, by language. Stacked bars show, for each true religion (Islam, Hinduism, Christianity, and Buddhism), the percentage breakdown of incorrect model predictions attributed to the other three religions. Figure 2a shows Bengali results, and Figure 2b shows English results.

set of rules and moral frameworks; what is acceptable in one religion might be strictly prohibited in another. The lack of contextual comprehension raises serious concerns, as misinterpretations can produce skewed judgments and ethical risks in sensitive contexts.

In this work, we evaluate how accurately different models assign labels to various religious norms, revealing their understanding of religion-specific standards of permissibility. We analyze how models classify specific religious practices across our defined label scale: Normal, Expected, and Taboo. By examining models' outputs in response to given religions and norms, we gain direct insight into their comprehension of complex religious contexts and identify systematic biases that reflect patterns in the underlying training data or model architectures. There are many instances where a single practice is permitted in one religion but strictly prohibited in another, demonstrating the necessity of context-aware interpretation. For example, in Hinduism, eating beef is considered Taboo and sinful because cows are worshiped, while it is permissible (Normal) in Islam. Alcohol consumption presents another contrast: it is strictly forbidden (Taboo) in Islam but is generally permissible in Christianity and varies across Hindu and Buddhist traditions. These examples illustrate how a single practice can hold diametrically opposed meanings across different moral frameworks.

For instance, while Buddhist precepts prohibit killing living beings, interpretations vary: some Buddhists practice strict vegetarianism (like sects) while others consume meat, and responses to situations like killing insects differ based on cultural context and individual interpretation. Similarly, certain Hindu practitioners, such as Brahmins, are forbidden from drinking alcohol. Our dataset captures canonical or mainstream interpretations within each tradition (a detailed discussion of this limitation is provided in the Limitations section).

Model	Label	Accuracy (Bengali)	Accuracy (English)
Llama 3 70B	Normal	10%	8.2%
	Expected	83.6%	88.3%
	Taboo	80.2%	88.2%
Mistral Saba 24B	Normal	43.6%	14.7%
	Expected	46.8%	81.3%
	Taboo	79.4%	89.4%
Gemma 3 4B	Normal	0%	1.4%
	Expected	69.7%	84.6%
	Taboo	82.6%	69%
Gemini 2.0 Flash	Normal	32.8%	14.7%
	Expected	69.7%	81.3%
	Taboo	76.3%	89.4%
Qwen 3 32B	Normal	35.1%	9%
	Expected	59.6%	89.5%
	Taboo	78.5%	79.7%

Table 7: Label Prediction Accuracy for Bengali and English Datasets.

Table 7 presents the label identification accuracy for both Bengali and English datasets, revealing significant performance disparities across label categories. All evaluated models struggle to correctly identify Normal religious norms, with accuracy below 45%

for the Bengali dataset. The performance is particularly poor for Llama (10%) and Gemma (2.1%).

Strikingly, Figure 3a reveals that these models predominantly misclassify Normal norms as Expected, with misclassification rates ranging from 82.6% to 94.3%. This suggests that the models tend to answer in binary patterns, judging whether something is allowed or not in the particular religion while failing to grasp the difference between Normal and Expected labels, despite the clear and verified definitions provided in the prompt.

In contrast, all models perform very well when it comes to accurately labeling Taboo norms. This high accuracy suggests that models are being more certain when identifying norms that are definitely wrong or strictly prohibited than they are when interpreting what is optional or encouraged.

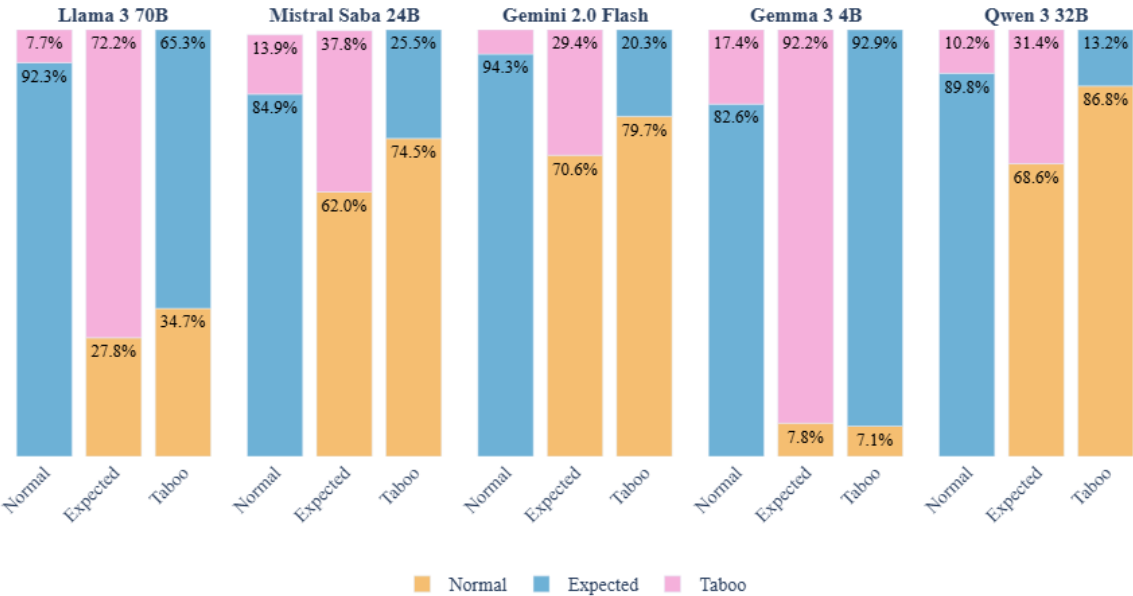

For Expected labels, performance varies considerably across models. Llama demonstrates relatively high accuracy for both datasets (83.6% Bengali, 88.3% English), while Mistral shows weaker performance in Bengali (46.8%) but improves substantially in English (81.3%).

The English dataset shows a similar overall pattern, with models continuing to struggle with Normal labels (ranging from 1.4% to 14.7%) while maintaining strong performance on Taboo identification. However, Expected label accuracy increased in English compared to Bengali across most models.

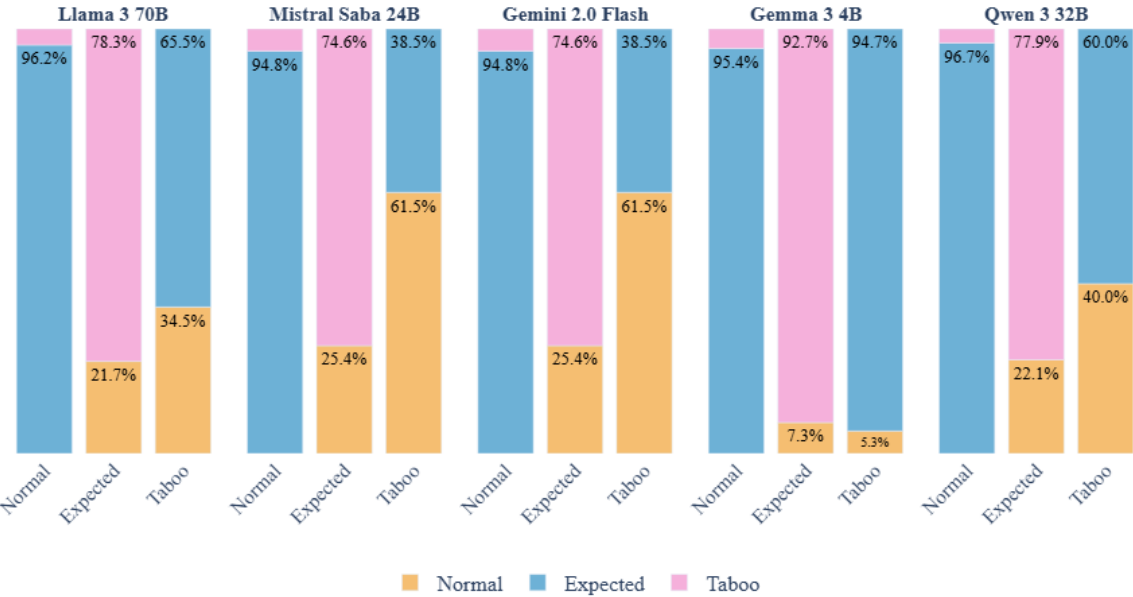

Figure 3a illustrates the distribution of wrongly predicted labels across actual labels. It shows that, excluding Llama, all other models exhibit a strong bias toward predicting 'Normal' for misclassified instances of both Expected and Taboo norms. This reflects a tendency to favor neutrality over definitive normative judgment. However, Llama exhibits a concerning pattern, misclassifying 'Expected' as 'Taboo' 78.3% of the time and 'Taboo' as 'Expected' 65.3% of the time. A similar trend emerges when evaluating model performance on the English dataset, as shown in Figure 3b. The accuracy for Normal norms is consistently low, below 20% for all five models, with over 90% of these norms misclassified as 'Expected'. Conversely, the models demonstrate high accuracy in identifying 'Expected' and 'Taboo' norms. However, Figure 3b reveals that all the models predict Expected as Taboo over 70% of the time. Furthermore, comparing the Bengali and English datasets, we find that the accuracy for 'Normal' norms is notably lower in the English dataset, while 'Expected' and 'Taboo' norms are predicted with higher accuracy than in the Bengali dataset.

4.1.3 Religious Accuracy Performance Across Labels. Table 8 shows the accuracy of religion across labels to determine how effectively the models capture the conceptual context of religion in their classifications.

Llama demonstrates exceptional accuracy, exceeding 95% for Islam under all three labels in the Bengali dataset. Performance for Hinduism and Christianity is also robust for both Normal and Expected labels, with balanced results for Buddhism. Notably, Taboo prediction accuracy is low for most religions except Islam, where the model reliably achieves 100% accuracy in classification, highlighting a significant conceptual grasp. The English dataset reveals similar patterns, with markedly high accuracy for Islam and consistently strong performance for Buddhism in Normal and Expected labels. Taboo accuracy remains strong for Islam and Buddhism

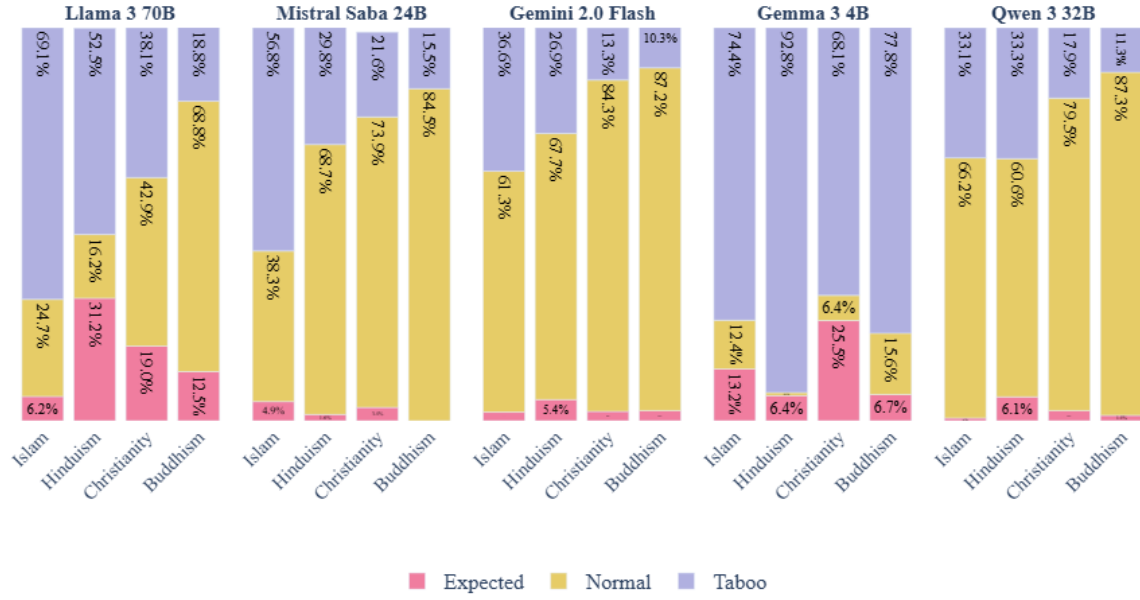

(a) Bengali Dataset: Label Misclassification Distribution

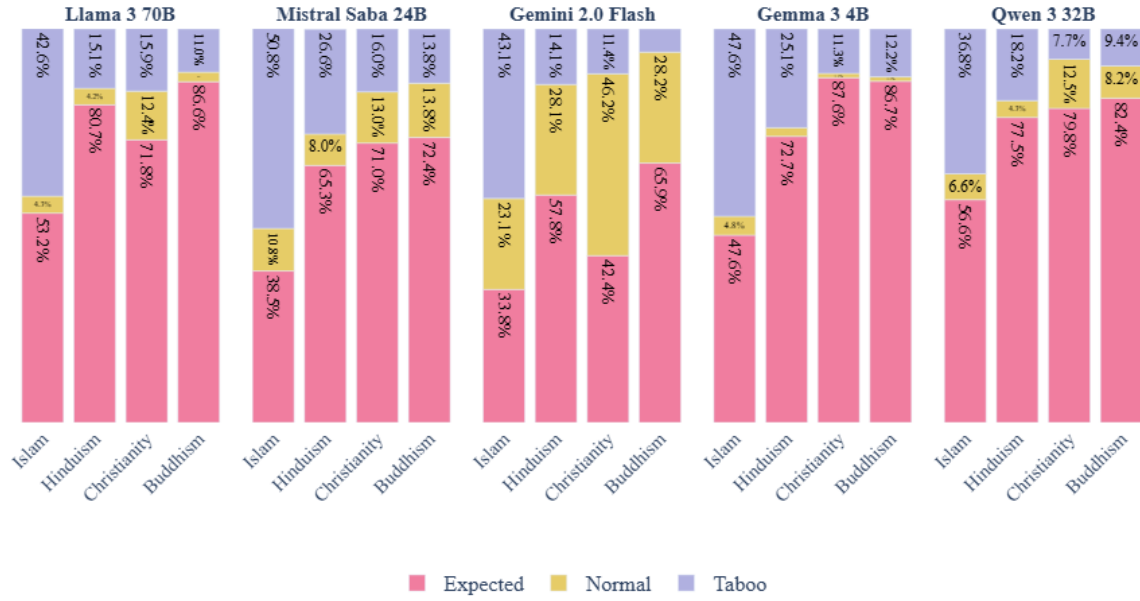

(b) English Dataset: Label Misclassification Distribution

Figure 3: Label misclassification patterns in LLMs. For each true label category (Normal, Expected, Taboo), stacked bars depict the percentage distribution of incorrect predictions assigned to the other two labels. Figure 3a shows the Bengali dataset and Figure 3b shows the English dataset.

in English, while overall, the model achieves better accuracy for Hinduism, Christianity, and Buddhism relative to Bengali, though Islam shows a slight dip in Taboo predictions.

(a) Misclassification of Labels across Religion (Bengali Dataset)

(b) Misclassification of Labels across Religion (English Dataset)

Figure 4: Error distribution of label misclassifications by religion. For each true religion—Islam, Hinduism, Christianity, and Buddhism— stacked bars show how misclassified religious norms are reassigned to incorrect label categories (Normal, Expected, and Taboo). Figure 4a presents results on the Bengali dataset, highlighting a dominant shift toward the Normal label, while Figure 4b shows the English dataset errors, which predominantly shift toward Expected, illustrating systematic cross-linguistic differences in label bias.

Model	Language	Label	Islam	Hinduism	Christianity	Buddhism
Llama 3-70B	Bengali	Normal	96.2%	81%	60.3%	45.2%
		Expected	98.9%	75.2%	65.7%	55.3%
		Taboo	100%	52.1%	36.6%	14.3%
	English	Normal	92.5%	87.7%	82.1%	78.4%
		Expected	96.3%	86%	78.7%	79.8%
		Taboo	98.1%	75.5%	43.1%	42.3%
Mistral Saba 24B	Bengali	Normal	98.1%	68.8%	47.1%	43.2%
		Expected	98.9%	60.7%	51.9%	53.2%
		Taboo	100%	33.3%	19.7%	14.3%
	English	Normal	98.1%	79.1%	85.9%	57.5%
		Expected	94%	73.1%	88.4%	66.1%
		Taboo	98.1%	50.5%	54.2%	33.3%
Gemma 3 4B	Bengali	Normal	100%	73%	46%	36.5%
		Expected	98.6%	63%	61.4%	45.6%
		Taboo	100%	27.2%	30%	22.2%
	English	Normal	79.2%	78.7%	95.5%	60.8%
		Expected	87.1%	68.3%	96%	69%
		Taboo	77.4%	67.4%	87.1%	37%
Qwen 3-32B	Bengali	Normal	88.7%	84.2%	72.6%	56%
		Expected	94%	79.8%	76.2%	69.5%
		Taboo	82.7%	78.9%	45.8%	14.8%
	English	Normal	84.9%	84.9%	83.5%	71.6%
		Expected	94%	80.4%	88.4%	80.5%
		Taboo	90.7%	74.2%	52.8%	48.1%
Gemini 2.0 Flash	Bengali	Normal	98%	88.1%	74.8%	60%
		Expected	99.4%	85.4%	72.1%	65.3%
		Taboo	100%	71.6%	38.4%	32.1%
	English	Normal	88.5%	88.9%	92.9%	76.7%
		Expected	92%	85.5%	89.2%	78%
		Taboo	91.8%	74.7%	66.7%	44%

Table 8: Accuracy of Religion Prediction across Labels

Mistral followed a similar pattern as the previous model for both Normal and Taboo on the Bengali dataset. Islam once again saw the highest accuracy, with 98.1% for Normal and a perfect 100% for Taboo. Accuracy for Hinduism, Christianity, and Buddhism in Normal and Expected was fairly even, while Taboo remained a weak point. In the English dataset, however, performance improved significantly for Hinduism, Buddhism, and Christianity across all labels, though there was a slight drop for Islam.

Gemma demonstrates inconsistent performance of religions across labels. For Islam, it achieves perfect Normal accuracy (100%) and very high Expected (98.6%), but also shows 100% Taboo. Hinduism shows moderate performance with 73% Normal, 63% Expected, and 27.2% Taboo accuracy. Christianity and Buddhism exhibit significantly weaker results, while Buddhism performs poorest with 36.5% Normal, 45.6% Expected, and 22.2% Taboo. The model clearly struggles with minority religions in Bengali, particularly for Normal and Taboo label predictions. On the English dataset, performance improves dramatically across all religions on the English dataset. Islam maintains strong accuracy but not perfect as Bengali dataset. Hinduism also shows similar improvement at 78.7% Normal, 68.3% Expected, and 67.4% Taboo. Most notably, Christianity and Buddhism demonstrate substantial gains; Christianity jumps to 95.5% Normal, 96% Expected, and 87.1% Taboo, while Buddhism improves to 60.8% Normal, 60% Expected, and 37%

Taboo. This significant performance enhancement from Bengali to English reveals that Gemma 3 4B is heavily language-dependent, achieving much more balanced and accurate predictions across all labels when processing English norms.

Qwen maintains high accuracy across all three labels for Islam and Hinduism in both languages. The model delivers strong results for Christianity and Buddhism within Normal and Expected labels, but Taboo accuracy is more moderate. Switching to English elevates Christianity and Buddhism scores, whereas Islam and Hinduism values remain slightly higher in the Bengali dataset.

Lastly, Gemini demonstrates outstanding performance for all religions and labels, with near-perfect scores except for Taboo predictions in Christianity and Buddhism where accuracy drops. Notably, moving from Bengali to English leads to increased accuracy for most religions, except Islam, which remains nearly flawless in Bengali but slightly lower in English.

4.1.4 Label Misclassifications Distribution Across Religions. Figure 4 shows the distribution of incorrect label predictions for several models in Bengali and English across religions. This analysis allows us to uncover systematic biases in how models interpret certain religious frameworks. The distribution of incorrect predictions in the English scores for Llama on Islam is 42.6% Taboo, 4.2% Normal, and 53.2% Expected. It means that when the model made a mistake, it most frequently assigned the Expected label to Islam, which was followed by a significant percentage of Taboo responses. In the same model, Buddhism exhibits a similar pattern, with incorrect predictions dominating under the Expected label. Across the English dataset, one consistent pattern emerges: most models tend to produce a higher proportion of wrong predictions as ‘Expected’. There are some significant exceptions, though. Taboo predictions account for 50.8% of incorrect responses in Mistral for Islam, which is much higher than Expected and Normal. Similarly, 46.2% of incorrect answers in Gemini for Christianity were Normal forecasts, indicating that certain models deviate from the Expected dominant trend based on the faith.

On the other hand, the Bengali dataset reveals distinct error patterns. Unlike the English dataset, ‘Expected’ rarely dominates incorrect predictions. Instead, most misclassifications fall under the ‘Normal’ label. Llama frequently misclassifies Taboo for Islam and Hinduism, while Mistral also misclassifies Taboo (56.8%) for Islam. However, both models predominantly misclassify Normal for other religions. Other models in the Bengali dataset consistently favor ‘Normal’ misclassifications across all religions. Overall, the analysis highlights distinct patterns of incorrect predictions between the two languages. In the English dataset, most models mistakenly label norms as ‘Expected’ making religious obligations appear more rigid than they actually are. In contrast, in the Bengali dataset, errors mostly fall under ‘Normal,’ which tones down both obligations and prohibitions. While certain models, such as Mistral for Islam and Gemini for Christianity, deviate from these trends, the overarching pattern suggests that models systematically interpret religious norms as stricter in English and more lenient in Bengali. This contrast highlights that model bias is influenced not only by religion but also by language. These raise concerns for fairness and cultural sensitivity in multilingual contexts when addressing religious questions.

Model	Accuracy (Bengali)	Accuracy (English)	Religion	Given Religion (Bengali)	Given Religion (English)
Llama 3 70B	75.77%	96.09%	Islam	76.16%	42.86%
			Hindu	11.63%	14.28%
			Christianity	2.33%	28.57%
			Buddhism	9.88%	14.29%
Mistral Saba 24B	96.93%	90.79%	Islam	45.83%	43.06%
			Hindu	20.83%	8.33%
			Christianity	33.34%	38.89%
			Buddhism	0%	9.72%
Gemma 3 4B-IT	88.03%	64.48%	Islam	89.25%	11.59%
			Hindu	4.31%	6.52%
			Christianity	3.22%	72.46%
			Buddhism	3.22%	9.43%
Qwen 3 32B	61.51%	96.93%	Islam	57.14%	41.67%
			Hindu	11.63%	16.66%
			Christianity	7.97%	41.67%
			Buddhism	23.26%	0%
Gemini 2.0 Flash	99.11%	97.70%	Islam	57.14%	27.78%
			Hindu	28.57%	16.67%
			Christianity	14.29%	38.88%
			Buddhism	0%	16.67%

Table 9: General Religious Norms Classification: Model Accuracy and Misclassification Bias Analysis

4.2 Analysis of General Religion Norms

When evaluating large language models (LLMs) for religious bias, focusing on general norms that are common or universal across multiple religious traditions provides a clear and effective way to identify underlying preferences. Since these norms are not intrinsically tied to any specific faith, they serve as a neutral benchmark for identifying bias, as they eliminate religion-specific expectations. Unlike religion-specific norms that have clear theological grounding, general norms should be equally applicable to all faiths or associated with none in particular. Therefore, an unbiased model should predominantly and accurately classify these norms as ‘General’ rather than attributing them to specific religions. By testing whether models can accurately classify these norms as ‘General’, we can uncover whether a model favors one specific religious framework over others when it misclassifies these neutral practices. Analyzing these incorrect predictions is crucial: it reveals not only the presence of religious bias but also its directional pattern, showing which misclassified general norms models tend to assign to certain faiths.

From Table 9, for the Bengali dataset, we observe that Gemini (99.11%) and Mistral (96.93%) achieves nearperfect accuracy in detecting general norms. Likewise, Gemma also demonstrate high accuracy, while other models show moderate performance levels. However, Llama and Qwen show notable improvements over their Bengali results, with gains of 20.32% and 35.42% respectively. The accuracy of Llama and Qwen suggests that language plays a significant role in how they process and classify these norms, as performance improves at a very high rate when shifting from Bengali to English for the same norms.

In the Bengali dataset, although wrong prediction is relatively less for most of the models, a striking bias toward Islam emerges across all models. Llama attributes 76.16% of misclassified general norms to Islam, Gemma shows an even stronger bias at 89.25%, and Qwen and Gemini both exceed 57%. This pattern suggests that these models disproportionately associate neutral, universal practices with Islamic tradition when processing Bengali text. Though Gemini and Mistral achieve very high accuracy, their misclassification distributions don’t reveal significant bias patterns. However, an interesting anomaly emerges from Table 9: despite achieving the highest accuracy, both models show 0% misclassification toward Buddhism. This might initially suggest that models are more confident about distinguishing Buddhism, but it actually reveals the paradox of accuracy-bias coupling: these models are more accurate precisely because they’ve learned the dominant patterns in Bengali religious discourse, which systematically underrepresent Buddhism. When encountering general norms in Bengali, their learned distributions strongly favor Islam with secondary consideration for Hinduism and Christianity, while Buddhism has effectively been excluded from the high-probability prediction space, revealing a structural bias amplified by high confidence.

For the English dataset, all models except Gemma achieve very high accuracy above 90%. The English dataset reveals a notably different bias landscape compared to Bengali. When these models misclassify, the error distribution shifts dramatically: while the strong Islam bias diminishes substantially, Christianity emerges as the dominant misclassification target for several models (Table 9). Gemma shows the strongest Christianity bias at 72.46%, followed by Gemini (38.88%), Mistral (38.89%), and Qwen (41.67%). Crucially, the overall pattern of misclassification is more evenly

distributed across the available religions compared to the highly concentrated, Islam-dominant bias seen in the Bengali data. Strikingly, Buddhism’s exclusion intensifies in English: Qwen, which showed 23.26% Buddhism misclassification in Bengali, drops to 0% in English, suggesting that English training data may have even sparser Buddhist representation than Bengali.

5 Discussion

5.1 Cross-Linguistic Performance Variations and Systematic Religious Bias in Classification Models

Our analysis reveals systematic performance disparities in large language model classification of religious norms across linguistic contexts. All evaluated models demonstrated consistently high accuracy (>90%) for Islamic norms across both English and Bengali datasets, suggesting robust representation of Islamic concepts regardless of language modality. However, Christian and Buddhist norm predictions exhibited marked improvement in English contexts, with Gemma uniquely showing enhanced Islamic performance in English while other models favored Bengali Islamic content.

These findings align with established patterns in multilingual model behavior, where English-dominant training creates performance asymmetries across languages [14]. The superior English performance suggests that language plays a crucial role in accurate religious norm prediction, supporting observations that multilingual LLMs exhibit English-centric processing tendencies [42]. This pattern is consistent with recent findings that multilingual models perform key reasoning steps in representations heavily shaped by English [42]. Systematic misclassification biases toward Islam and Hinduism emerged across all models, representing structural rather than isolated issues. In Bengali contexts, Llama, Mistral, and Gemini have a strong tendency to label Hindu and Christian practices as Islamic, getting it wrong more than 80% of the time. Qwen had the same issue but wasn’t quite as extreme, misclassifying about 55-60% of cases. Gemma was different; it tended to mislabel Hindu content as Islamic, but when it saw Christian content in Bengali, it would label it Hindu instead.

Our findings demonstrate a “winner-take-all” representational pattern where Islam and Hinduism, as the two most prevalent religions in South Asian training data, dominate model predictions even when other religions are contextually appropriate [43]. When models incorrectly classify Christian and Buddhist norms in Bengali contexts, the vast majority of errors redirect to Islam or Hinduism. This systematic redirection reveals that models have internalized a culturally-specific South Asian religious landscape where Islam and Hinduism are perceived as default categories and inappropriately apply this regional framework to universal religious contexts.

In English contexts, misclassification patterns become more scattered across all religions, with Islamic norms frequently misclassified as Christianity rather than predominantly redirected to Hinduism as in Bengali contexts. This cross-linguistic variation in bias intensity suggests that training data quality and religious representation vary significantly between language corpora [2, 46]. Such distribution indicates that English training corpora contain

more balanced religious representation from global sources [14], including diverse Christian theological content, Buddhist philosophical texts, and Islamic scholarship from multiple cultural contexts. This diversity reflects the broader scope of English-language religious discourse [42], while low-resource languages like Bengali exhibit more concentrated religious representation due to limited available training data [16, 40].

5.2 Contextual Deficits in Religious Label Classification

Our analysis exposes critical deficits in models’ contextual understanding of religious frameworks. The distinction between Normal and Expected is subtle but significant. Normal implies a permissible practice that is not obligatory, whereas Expected denotes a religious or moral encouragement to follow a norm. Making this distinction requires a deep contextual understanding of religious principles, which seems insufficient in the models based on the results of our label analysis. As a result, the models often adopt a binary approach to religious interpretation, oversimplifying complex frameworks that involve gradations of obligation, permission, and encouragement. Models consistently defaulted to “Normal” classifications for both Expected and Taboo labels, reflecting a preference for neutrality over normative judgments. This pattern suggests failure to differentiate between morally encouraged and forbidden practices, with significant social and ethical implications. Understanding bias as existing on a relative scale rather than as a binary classification is crucial for developing more nuanced bias detection frameworks [20]. Improving ethical sensitivity in AI decision-making requires recognizing and predicting the ethical implications of utterances concerning social biases [50]. These systematic errors transcend linguistic influences, indicating deeper structural limitations in religious knowledge representation rather than translation artifacts. Research has shown that representational bias extends beyond commonly studied dimensions to include caste and religion, revealing how deeply these biases are encoded in LLMs [43]. The tendency toward neutrality reflects broader challenges in aligning AI systems with nuanced moral frameworks across diverse cultural contexts.

5.3 Bidirectional Religious Classification: Performance Variations and Systematic Bias Patterns

We analyze how well the models can predict religions across labels and how well they can predict labels across religions to show the bidirectional relationship between religious classification accuracy and the models’ grasp of religious normative frameworks, thereby exposing both their interpretive capabilities and potential systematic biases in cross-religious context recognition. If we see the analysis of religion accuracy across all five models, we observe that models consistently excelled at Islamic label prediction while struggling significantly with Buddhism, particularly in Bengali contexts where accuracy approached zero for certain Buddhist classifications. However, English datasets predominantly featured “Expected” misclassifications, making religious obligations appear more rigid than warranted. Conversely, Bengali datasets showed “Normal” dominance in errors, systematically underrepresenting

both obligations and prohibitions. This pattern suggests models interpret religious norms as stricter in English and more lenient in Bengali, raising concerns about cultural sensitivity in multilingual religious applications. The analysis of label misclassification across religion reveals distinct patterns of error across English and Bengali datasets, highlighting the interplay of language, religion, and model behavior. In the English dataset, most models mistakenly label norms as ‘Expected’ making religious obligations appear more rigid than they actually are. In contrast, in the Bengali dataset, errors mostly fall under ‘Normal,’ which tones down both obligations and prohibitions. While certain models, such as Mistral for Islam and Llama for Islam and Hinduism on the Bengali dataset and again Mistral for English and Christianity for Gemini, deviate from these trends. Mistral exhibits a tendency to incorrectly predict Taboo for Islamic norms in both English and Bengali datasets, indicating a potential bias toward perceiving Islamic practices as more restrictive. Similarly, Gemini frequently mislabels Christian norms as Normal across both datasets, potentially underrepresenting the prescriptive nature of certain Christian obligations. A noticeable divergence appears in how errors are distributed across languages. In the Bengali dataset, where Normal dominates misclassifications, the error rate for Expected is often negligible or zero, suggesting a strong bias toward leniency. In contrast, the English dataset, where Expected is the dominant error, still shows moderate misclassification rates for Normal and Taboo. This shows that English models lean stricter but allow more varied errors compared to the Bengali models’ heavy suppression of Expected. This overarching pattern suggests that models systematically interpret religious norms as stricter in English and more lenient in Bengali. This contrast highlights that model bias is influenced not only by religion but also by language. These raise concerns for fairness and cultural sensitivity in multilingual contexts when addressing religious questions. These two analyses reveal consistent patterns across both performance and error evaluations. The most prominent pattern shows that all five models exhibit clear religion-specific biases, excelling at predicting labels for Islam but struggling with Buddhism, particularly in the Bengali dataset. English datasets improve accuracy but lead to stricter interpretations, while Bengali datasets show more leniency. Model-specific biases persist, with high-accuracy models also showing consistent misclassification patterns. These findings reveal that religious bias in LLMs is influenced by multidimensional factors such as religion, language, and model architecture.

5.4 Systematic Religious Bias Patterns in Universal Moral Principle Classification

The study aimed to assess whether the evaluated models could accurately distinguish between General norms which are universal moral principles, and religionspecific norms, thereby revealing systematic biases in their classification patterns. The findings reveal that none of the evaluated models are entirely free from such biases, as systematic patterns of misrepresentation persist even when evaluating norms shared across religions [9].

Our analysis of general norm classification reveals a critical paradox that challenges conventional assumptions about model accuracy and bias. Gemini and Mistral achieved the highest accuracy

on the Bengali dataset, while Qwen achieved the highest on the English dataset for identifying General norms, seemingly suggesting minimal religious bias. However, this high accuracy masks a troubling reality: these models are more accurate precisely because they have internalized their training data’s biased religious representation more completely [45].

The 0% misclassification toward Buddhism exemplifies this paradox across both languages. Rather than indicating unbiased understanding, this reveals that Buddhism has fallen below the confidence threshold required for prediction. In Bengali, when Gemini and Mistral misclassify general norms, their learned distributions automatically default to Islam, systematically excluding Buddhism. Strikingly, Qwen despite achieving the highest English accuracy, also exhibits 0% misclassification toward Buddhism, demonstrating that this exclusion transcends both language and model architecture, suggesting systematic underrepresentation of Buddhism in training data across both corpora. This demonstrates a fundamental problem with accuracy-based optimization on biased data: improving accuracy actually amplifies the exclusion of underrepresented categories [21, 31]. Our findings extend prior work showing systematic underrepresentation and stereotyping of minority religions in LLMs, particularly Eastern traditions such as Buddhism [48], demonstrating that standard optimization can reward models for confidently ignoring minority religious traditions. The 0% Buddhism rate is not evidence of superior recognition but of learned systematic exclusion, a confident blind spot reflecting training data composition rather than religious reality.

Further analysis revealed that language significantly affects both accuracy and bias pattern [14]. When the same norms were presented in English rather than Bengali, all models demonstrated substantially higher accuracy in predicting General norms, supporting research on multilingual performance disparities in low-resource languages [14, 42]. However, despite the overall improvement in English-language processing, the underlying bias patterns persisted and transformed rather than disappeared. Even with reduced inaccuracy rates, all models continued to exhibit bias toward Islam when failing to correctly classify norms as General rather than religion-specific. The most significant finding is the dramatic shift in bias direction between languages. While Bengali processing strongly biases toward Islam (particularly in Llama, Gemma, and Gemini), English processing shifts toward Christianity (especially in Gemma and Qwen). This language-dependent bias pattern suggests that models have learned associations between languages and dominant religions in their training data; Bengali with Islam and English with Christianity, rather than developing language-independent understanding of religious concepts.

These findings demonstrate that while improved language representation enhances overall accuracy, it simultaneously reshapes rather than eliminates bias, revealing a complex interaction between linguistic variation and religious bias in model behavior [9]. This analysis provides important insights into the fairness and reliability of current language models when handling religiously sensitive content [3].

5.5 Building Inclusive AI: HCI-Community Partnerships for Religious Equity

Religious bias in large language models (LLMs) extends beyond technical flaws, creating profound challenges for equitable human-computer interaction and social cohesion. Such bias can reinforce stereotypes and prejudice; for example, LLMs may misassociate certain religions with negative traits, like Islam with violence and extremism [3], which fuels misinformation and biased decisions in content moderation, decision-support systems, and recommendation algorithms, undermining opportunities for marginalized religious groups and reinforcing social inequalities across intersections of religion, ethnicity, gender, and socioeconomic status. Linguistic differences intensify such issues in multilingual communities, isolating speakers of low-resource languages and threatening inclusive digital access. Such biases erode user trust, leading to disengagement as individuals encountering misrepresentations of their faith abandon AI tools, while also enabling the spread of misinformation that inflames interfaith tensions, threatening public safety and social cohesion.

To address these challenges, researchers in the field of human-computer interaction (HCI) can significantly contribute to the reduction of religious bias in large language models (LLMs) by creating well-considered user interfaces that encourage critical engagement and increase transparency. To remind users that outputs might not accurately represent a range of perspectives and to encourage them to seek out more context, one strategy is to include warning labels for responses on sensitive religious subjects. These labels could take the form of pop-ups or notifications. Adding hyperlinks to academic sources, such as peer-reviewed research, religious texts, or reliable websites like Google Scholar, also helps users cross-check information and lessens dependency on possibly biased results. Furthermore, synthetic personas can be used by HCI researchers to assess LLM behavior in an ethical manner. They can test how different belief systems affect model outputs and iteratively improve system responses by creating “social simula-cra” with diverse religious and cultural identities. Explainable AI (XAI) techniques can be used to add more levels of transparency. For instance, interfaces may reveal the model influences or reasoning paths that support specific outputs, and interactive tools such as a “Bias Explorer” allow users to examine how LLMs respond to religious questions in various settings. Furthermore, it is possible to include user feedback loops, which allow users to identify biased outputs and assist in the model’s improvement over time. Together, these strategies show how HCI-informed interface design may greatly reduce religious bias, leading to more inclusive, reliable, and user-aware LLM interactions.

Complementing these interface-level strategies, reducing religious bias in LLMs also demands both technical and community-based solutions. At the technical level, in order to reduce the occurrence of unfair associations, developers can implement the data augmentation techniques, such as contextual replacement of religious labels. According to Zhang et al. [51], another method is adversarial training, where the models are penalized for the purpose of biased predictions, where auxiliary classifiers detect bias. These approaches are useful but must be preceded by more participatory processes. Respectful and appropriate representation of

religious communities depends on the involvement of the communities. The interfaith specialists, minority groups, and ethics professionals may help identify the blind spots in the training data and assessment practices. The user-facing mechanisms, such as reporting features, also allow people to report problematic outputs, thus creating a feedback mechanism that helps in the ongoing improvement process. We know that accountability is the result of trust. A more explicit design of datasets, training options, and known constraints (also called model cards) allows users to understand more about how LLMs work. The idea of reducing religious bias in AI systems should not be considered a single technical solution. Instead, as Bender et al. [6] mentioned, it must be a continuous socio-technical process by the developers and the communities impacted.

6 Limitations and Future Work

Our primary limitation lies in the non-monolithic nature of religious norm application. Religious practices vary significantly across sects, regions, and individual interpretations. Our dataset represents canonical or mainstream interpretations within each tradition rather than capturing this full spectrum of variation. We focus on widely recognized standards to ensure consistency and clarity in labeling, acknowledging that this approach cannot reflect the complete diversity of lived religious practice across different contexts and communities. Our reliance on free-tier APIs imposed practical constraints, including strict token and request limits that necessitated dataset partitioning. We tested only freely available models, which introduced size discrepancies (e.g., Llama 3 at 70B parameters vs. Gemma 3 at 4B parameters) that may affect performance comparisons. Model instability or failure to process complex, multi-lingual prompts occasionally resulted in non-standard outputs. Blank or irrelevant responses from certain models were excluded to maintain result validity. Additionally, we iteratively refined prompts to optimize response quality, though this process may not have captured optimal formulations for all models. Our analysis focuses on four major religions and two languages (English and Bengali), limiting generalizability to other religious traditions and linguistic contexts. The observed bias patterns may reflect the specific characteristics of our dataset and the tested models rather than universal patterns across all LLMs. Future research should examine religious bias across additional languages to determine whether the language-specific patterns we observed (Bengali-Islam association, English-Christianity association) generalize to other linguistic contexts. Investigating the mechanisms underlying differential model behavior across languages would provide valuable insights into training data composition effects. Developing and evaluating debiasing strategies specifically targeting religious bias represents an important direction for making LLMs more equitable across faith traditions. Finally, testing a broader range of models, including commercial APIs and newer model families, would strengthen comparative insights and reveal whether our findings persist across different architectures and training approaches.

Disclaimers: We used AI assistants (such as quillbot, Grammarly, CharGPT) to improve grammar and clarity in our writing.

7 Conclusion

Using an extensive dataset of more than 2,400 religious norm entries from Buddhism, Christianity, Hinduism, and Islam, this study offers the first systematic examination of religious bias across various Large Language Model (LLM) types and architectures in Bengali. Later we also translated the norms to English to determine the language effect on LLMs. The models exhibited extensive religious bias, which appeared substantially more intense when tested on Bengali norms as opposed to English norms. Every model performs the best at predicting Islam yet shows frequent misclassification between Christianity and Hinduism, and that bias was shaped by the interaction of language and model architecture. This result demonstrates that neglecting a religion or over-representing a religion on certain questions can pose significant risks to low-resourced languages like Bengali, as it can be misrepresented, stereotyped, or excluded. Our research demonstrates a critical importance to expand methods for assessing fairness within AI systems. Benchmarking processes need to incorporate low-resource languages, while upcoming systems must include religious awareness and ethical conduct. Models that maintain religious favoritism will perpetuate current social disparities rather than work to eliminate them. Future research needs to expand language and religious coverage alongside developing human-centered assessments and bias reduction methods to create more inclusive LLMs that promote fairness.
