

CONCENTRATION BOUNDS FOR INTRINSIC DIMENSION ESTIMATION USING GAUSSIAN KERNELS

MARTIN ANDERSSON

ABSTRACT. We prove finite-sample concentration and anti-concentration bounds for dimension estimation using Gaussian kernel sums. Our bounds provide explicit dependence on sample size, bandwidth, and local geometric and distributional parameters, characterizing precisely how regularity conditions govern statistical performance. We also propose a bandwidth selection heuristic using derivative information, which shows promise in numerical experiments.

1. INTRODUCTION

In this paper we address the problem of reliably estimating the *intrinsic dimension* d of a d -dimensional Riemannian submanifold $\Omega \subset \mathbb{R}^N$ from i.i.d. observations X_1, \dots, X_n drawn from a distribution p supported on Ω , where d is the dimension of the tangent space $T_x\Omega$. This problem arises across data analysis, from characterizing strange attractors [1] to understanding generalization in neural networks [2, 3]. In addition, many dimensionality reduction algorithms require dimension estimates as input [4, 5, 6].

Dimension estimation from finite samples is, however, fundamentally ambiguous: any point set admits embeddings in manifolds of varying dimensions, as in Fig. 1. To obtain rigorous estimates of d , we must therefore impose regularity conditions on the geometry of Ω and the distribution p . The central question we address is:

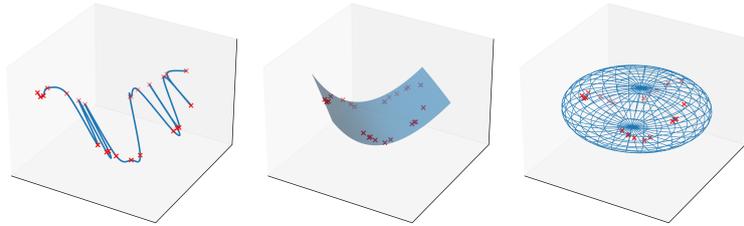

FIGURE 1. Same point set embedded as a 1D curve, 2D surface, and 3D volume, illustrating the need for regularity assumptions.

How do sample size, dimension, and regularity assumptions on the geometry and distribution affect the statistical performance of Gaussian kernel-based dimension estimators?

Such Gaussian kernel-based estimators were proposed in [7]. Their approach uses the Gaussian kernel $K_t(x, y) = e^{-\|x-y\|^2/t}$ and the global kernel sum over all pairs:

$$S(t) = \frac{1}{n^2} \sum_{i,j=1}^n K_t(X_i, X_j).$$

For small *bandwidth* t and large n , the expected value $\mathbb{E}[K_t(X_1, X_2)]$ scales approximately as $\pi^{d/2}t^{d/2}$, suggesting the dimension can be estimated from the

slope of $\log S(t)$ versus $\log t$. Specifically, for appropriately chosen bandwidths $t_1 < t_2$, one estimates

$$(1.1) \quad d \approx 2 \frac{\log S(t_2) - \log S(t_1)}{\log(t_2) - \log(t_1)}.$$

A central problem here is at what scale to choose the bandwidths t_1, t_2 : If too small, the effective radius of the kernel does not capture enough points, and if too large the kernel sum saturates and asymptotes to being constantly 1. We need a scale at which the power-law dimensional scaling approximately holds. Moreover, the global estimator in (1.1) provides only a single dimension estimate for the entire dataset, which fails when Ω has varying local dimension or when p is highly non-uniform.

We therefore study the *local* kernel sum at a point $x \in \Omega$:

$$S(x, t) = \frac{1}{n} \sum_{j=1}^n K_t(x, X_j),$$

and the corresponding local dimension estimator

$$(1.2) \quad \hat{d}(x, t) := 2 \frac{\log S(x, 2t) - \log S(x, t)}{\log 2}.$$

While it is known that this estimator concentrates to d for sufficiently large n and appropriate choice of t , an explicit dependence on sample size, dimension, bandwidth, and the regularity of Ω and p is, to our knowledge, novel.

On a more practical side, many dimension estimators perform better than worst-case theoretical guarantees suggest, see [8]. When applications do not require absolute rigor, heuristic approaches to hyperparameter selection remain valuable. One of the most common kernels used is the indicator kernel, going back to [1]. For this kernel there are varying heuristics for bandwidth (radius in this case) selection, such as using the distance to the k -nearest neighbor of x , k being some fraction of n [9]. One reason the smooth Gaussian kernel can improve on indicator-kernel heuristics is that it enables using derivative information in bandwidth selection. We propose one such method in this paper.

Our contributions:

- (1) We establish concentration bounds (Theorem 2) showing $\hat{d}(x, t)$ concentrates around d with constants having explicit dependence on geometric parameters, bandwidth, regularity of distribution and sample size.
- (2) We prove anti-concentration bounds (Theorem 4, again with explicit dependence on parameters), which upper-bounds the probability $\mathbb{P}(|\hat{d} - d| \leq \varepsilon)$ that the estimator is within ε of the true dimension, thereby giving a lower bound on the precision scale ε at which concentration can occur.
- (3) We propose a bandwidth selection heuristic (Algorithm 1) illustrating how derivative information, unavailable for indicator kernels, might be utilized. It shows promise in limited experiments.

Paper organization: Section 2 reviews related work on dimension estimation. In Section 3 we explain our setup, and in Sections 3.1 and 3.2 we state and prove our results. Section 4 provides some numerical experiments, and Section 5 concludes our paper. Most proofs are in Sections A and B.

2. BACKGROUND AND RELATED WORK

In the following, we review the most relevant prior work. There are many ways to estimate intrinsic dimension, and one can broadly categorize estimators according to the type of geometric information used [8].

One such family of estimators can be classified as *tangential estimators* [8]. These use the fact that locally, a smooth d -dimensional manifold looks like a graph over its tangent space. This implies that around a point $x \in \Omega$, points should cluster close to a d -dimensional affine space. These methods aim to find this affine space and from there estimate the dimension. These include principal component analysis (PCA) and local PCA [10, 11].

The estimator (1.2) is instead a type of *parametric* estimator. These generally work by locally approximating with uniform density and flat geometry. Under these circumstances many geometric quantities have probability distributions for which the dimension d is a parameter, which one can estimate by different methods.

A classical example of this is using volume growth. Suppose we have n i.i.d. samples, $X_1, \dots, X_n \in \Omega$, and a point $x \in \Omega$ with density $p(x)$. Define the indicator kernel $K_r(x, y) := \mathbf{1}_{\|x-y\| \leq r}$, let $B_r(x)$ denote the ball of radius r centered at x and $V(\cdot)$ the volume function. Then for large n and small r ,

$$\frac{1}{n} \sum_i K_r(x, X_i) \approx \mathbb{P}(X_1 \in B_r(x)) \approx p(x)V(B_r(x)) = p(x)V(B_1(x))r^d,$$

and $\frac{\frac{1}{n} \sum_i K_{r_2}(x, X_i)}{\frac{1}{n} \sum_i K_{r_1}(x, X_i)} \approx (r_2/r_1)^d$. This expected scaling can be used to estimate d , as was done with the correlation integral, introduced in [1],

$$(2.1) \quad C(r) = \frac{1}{n^2} \sum_{i,j} K_r(X_i, X_j).$$

To estimate, one chooses two scales r_2, r_1 and examines the scaling of the quotient $C(r_2)/C(r_1)$. However, knowing which scales r_2, r_1 to use is both a practical and theoretical challenge.

Instead of examining how the count of neighbors or kernels sums scale with bandwidth, many estimators instead fix the number of neighbors k and use the k -nearest neighbor distance as radius. The authors in [9] developed a nearest-neighbor ratio estimator with exponential finite sample guarantees. Their estimator takes the form

$$(2.2) \quad \hat{d}(x) = \frac{\log(2)}{\log(\hat{r}^{(k)}(x)/\hat{r}^{(\lceil k/2 \rceil)}(x))}$$

where $\hat{r}^{(k)}(x)$ denotes the distance from x to its k -th nearest neighbor. This works similarly as above, that for large n ,

$$k/n \approx \mathbb{P}(X_1 \in B_{\hat{r}^{(k)}}(x)) \propto (\hat{r}^{(k)})^d.$$

Then $\hat{r}^{(k)}/\hat{r}^{(\lceil k/2 \rceil)} \approx 2^{1/d}$, yielding the dimension estimate above. Once more one faces the problem of choosing hyperparameters, in this case k , which is important for performance.

The correlation integral closely resembles the estimator (1.1), the main difference being the choice of kernel. One can generalize this type of estimator to wider classes of kernels. In [12], they proved that compactly supported kernels on manifolds with curvature and varying distributions asymptotically have the correct scaling. Our work differs in providing finite-sample concentration bounds with explicit constants for the non-compactly supported Gaussian kernel, thereby characterizing the dependence on sample size and geometric regularity.

The choice of focusing on kernel-based methods here, and specifically the Gaussian kernel, is motivated by their general usefulness in extracting geometric and topological properties of data manifolds. This is a rich and well-established area of research, with some examples being the diffusion maps framework [13], Laplacian eigenmaps [14], kernel PCA [15], and spectral clustering [16], which all leverage kernel functions to capture intrinsic geometric structures from data samples on

manifolds, with the Gaussian kernel being a common choice. One key property of this kernel is its smoothness (exploited in Section 3.3).

Kernel-based methods often require dimension estimates for parameter selection (e.g., number of eigenvectors in spectral methods, manifold dimension in diffusion maps), motivating rigorous theoretical analysis of kernel-based dimension estimation.

Regarding heuristics in bandwidth selection, [7] visually inspected the log-log plot to find the linear region. In a refinement, [6, 17] developed this into a more automatic condition, and suggested choosing a bandwidth that maximizes the slope of the log-log plot. More specifically, they create a dyadic partition of an interval $[t_0, t_1]$, evaluate the numerical derivative

$$(2.3) \quad \frac{\log(S(x, 2t)) - \log(S(x, t))}{\log(2)},$$

and choose t to maximize the slope. We try to improve on this in Section 3.3, and we are not aware of similar approaches to bandwidth selection in the context of dimension estimation.

3. METHODOLOGY AND MAIN RESULTS

We now formalize our setup and state the main results. In everything that follows, we assume $X_1, X_2, \dots, X_n \in \Omega \subset \mathbb{R}^N$ are i.i.d. random variables with K -Lipschitz density p (with respect to the ambient Euclidean metric in \mathbb{R}^N) supported on a d -dimensional manifold $\Omega \subset \mathbb{R}^N$. We assume access to some fixed point $x \in \Omega$ (which could always be taken from the sample itself). We consider the kernel $K_t(x, y) = \exp\left(-\frac{\|x-y\|^2}{t}\right)$, and refer to the parameter t as the bandwidth. We define the normalized kernel sum

$$(3.1) \quad S(x, t) := \frac{1}{n} \sum_{i=1}^n K_t(x, X_i).$$

Let $p(x)$ be the density of a point x . Then, for small t and under suitable geometric conditions on the manifold (which we make precise below),

$$(3.2) \quad \mathbb{E}[K_t(x, X)] \approx p(x) \pi^{d/2} t^{d/2}.$$

For large n , the law of large numbers gives $S(x, t) \approx \mathbb{E}[K_t(x, X)]$, explaining the power-law scaling $S(x, t) \propto t^{d/2}$ and the linear relationship $\log S(x, t) \approx \text{const} + (d/2) \log t$.

From these considerations we define the estimator

$$(3.3) \quad \hat{d}(x, t) = 2 \frac{\log(S(x, 2t)) - \log(S(x, t))}{\log(2)}.$$

To make our bounds explicit, we need to quantify how 'well-behaved' the manifold Ω is. We do this through three local parameters: L controls how much Ω curves away from its tangent space, M controls volume distortion, and r ensures Ω doesn't fold back on itself. Formally:

Definition 3.1 (Local (L, M, r) -regularity). Let $\Omega \subset \mathbb{R}^N$ be a smooth d -dimensional submanifold. We say Ω is *locally (L, M, r) -regular at $x \in \Omega$* if there exist constants $L, M \geq 0$ and $r > 0$ such that in the ball $B_r(x)$, there exists a smooth orthogonal projection map $\pi : B_r(x) \cap \Omega \rightarrow B_r(x) \cap (x + T_x \Omega)$ satisfying:

- (i) For all $y \in B_r(x) \cap \Omega$ with $z = \pi(y) - x \in T_x \Omega$ and $h_z = \pi(y) - y$:

$$\|x - y\|^2 = \|z\|^2 + \|h_z\|^2, \quad \|h_z\| \leq L \|z\|^2$$

- (ii) The volume distortion satisfies $(1 - M\|z\|^2) \leq V(y) \leq (1 + M\|z\|^2)$ where $V(y)$ is the Jacobian determinant of π^{-1} .

Remark 3.2. The graph bound implies $|V - 1| = \mathcal{O}((L\|z\|)^2)$, but we keep separate constants to simplify.

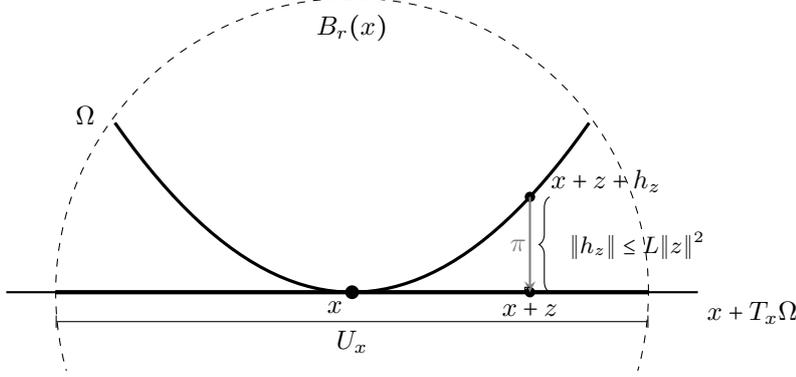

FIGURE 2. (L, M, r) -regular at x : $\Omega \cap B_r(x)$ projects orthogonally onto $U_x = x + T_x\Omega \cap B_r(x)$.

This particular formulation is also useful for our analysis, as we frequently change variables via the projection π and need explicit control over the resulting distortion.

Here follows a simple example where we calculate these parameters.

Example 3.3 (Circle of radius R). Let $\Omega = \{(x, y) \in \mathbb{R}^2 : x^2 + y^2 = R^2\}$ be the circle of radius R .

Consider the point $x = (R, 0)$. The tangent space at x is vertical: $T_x\Omega = \text{span}\{(0, 1)\}$, and the normal space is horizontal: $(T_x\Omega)^\perp = \text{span}\{(1, 0)\}$.

The orthogonal projection is $\pi_x(a, b) = (R, b)$. The inverse is

$$\pi_x^{-1}(R, t) = (\sqrt{R^2 - t^2}, t) = (R, t) + (\sqrt{R^2 - t^2} - R, 0),$$

for $|t| \leq R/2$.

We expand $\sqrt{R^2 - t^2} = R\sqrt{1 - t^2/R^2} = R - \frac{t^2}{2R} + \mathcal{O}(t^4/R^3)$, which gives

$$h_z = (R, t) - (\sqrt{R^2 - t^2}, t) = (R - \sqrt{R^2 - t^2}, 0) = \left(\frac{t^2}{2R}, 0\right) + \mathcal{O}(t^4/R^3),$$

which satisfies $\|h_z\| \leq \frac{1}{R}\|z\|^2$ for $z = (0, t)$.

The arc length element is $ds = \frac{R dt}{\sqrt{R^2 - t^2}} = 1 + \frac{t^2}{2R^2} + \mathcal{O}(t^4/R^4)$, giving Jacobian $V = 1 + \frac{t^2}{2R^2} + \mathcal{O}(t^4/R^4)$.

Thus, the conditions of Definition 3.1 hold with $L = \frac{1}{R}$, $M = \frac{1}{R^2}$ and $r = R/2$.

Remark 3.4. There is of course the question of how to estimate or know these parameters from data alone. This is beyond the scope of this paper; we simply note that our geometric control relates to the notion of *reach* of a manifold, and there are methods [18] that estimate this quantity.

In the rest of this paper, we assume that Ω is locally (L, M, r) -regular at each point $x \in \Omega$ where we estimate the dimension.

3.1. Concentration bounds. With the setup of the previous section we proceed with our main theoretical results. The first is a concentration inequality, and the main tool we use is Bernstein's inequality:

Theorem 1 (Bernstein's inequality). *Let X_1, \dots, X_n be independent random variables with finite variance such that $|X_i - \mathbb{E}[X_i]| \leq b$ for some $b > 0$ almost surely for all $i \leq n$. Let*

$$S = \sum_{i=1}^n (X_i - \mathbb{E}[X_i]),$$

and $v = \sum_{i=1}^n \text{Var}[X_i]$. Then

$$\mathbb{P}(S \geq \varepsilon) \leq \exp\left(\frac{-\varepsilon^2}{2(v + b\varepsilon/3)}\right).$$

The major work of this section consists in finding bounds on the expectation and variance of certain random variables whose structure emerges from decomposing the tail probabilities $\mathbb{P}(\hat{d} - d \geq \varepsilon)$ and $\mathbb{P}(\hat{d} - d \leq -\varepsilon)$, where $\varepsilon > 0$ is our target precision. If we define

$$\begin{aligned} W_i^+ &= K_{2t}(x, X_i) - 2^{(d+\varepsilon)/2} K_t(x, X_i) \\ W_i^- &= K_{2t}(x, X_i) - 2^{(d-\varepsilon)/2} K_t(x, X_i). \end{aligned}$$

Then, by direct calculation,

$$\begin{aligned} \mathbb{P}(\hat{d} - d \geq \varepsilon) &= \mathbb{P}\left(\frac{2}{\log 2} \log \frac{S(x, 2t)}{S(x, t)} - d \geq \varepsilon\right) \\ &= \mathbb{P}(S(x, 2t) - 2^{(d+\varepsilon)/2} S(x, t) \geq 0) \\ (3.4) \quad &= \mathbb{P}\left(\frac{1}{n} \sum_{i=1}^n W_i^+ - \mathbb{E}[W_i^+] \geq -\mathbb{E}[W_i^+]\right) \end{aligned}$$

and similarly for the lower bound, giving us

$$(3.5) \quad \mathbb{P}(\hat{d} - d \leq -\varepsilon) = \mathbb{P}\left(\frac{1}{n} \sum_{i=1}^n W_i^- - \mathbb{E}[W_i^-] \leq -\mathbb{E}[W_i^-]\right).$$

In this form, the probabilities we need to bound are linear in X_1, \dots, X_n . From the preceding, we see that we need to understand

$$(3.6) \quad W^+ = K_{2t}(x, X) - 2^{(d+\varepsilon)/2} K_t(x, X)$$

and

$$(3.7) \quad W^- = K_{2t}(x, X) - 2^{(d-\varepsilon)/2} K_t(x, X),$$

where $X \sim p$.

In order to apply Bernstein's inequality we need to control expectation and variance of W^+ and W^- . We do this by controlling the moments of K_t and K_{2t} . To achieve the latter, a useful property of Gaussian kernels is that products satisfy

$$(3.8) \quad K_a(x, y) K_b(x, y) = K_{ab/(a+b)}(x, y),$$

and in particular $K_a(x, y)^m = K_{a/m}(x, y)$.

The following lemma addresses how the geometric parameters L, M, r , Lipschitz constant K , and chosen bandwidth affect deviation from the ideal scaling of (3.2):

Lemma 3.5 (General Moment Bounds). *Fix $x \in \Omega$ with $\text{dist}(x, \partial\Omega) > 0$ (or $\partial\Omega = \emptyset$). Let $\gamma \in (\frac{1}{4}, \frac{1}{2})$, denote $r_0 = t^\gamma$ and assume $X \sim p$. Then for any $t > 0$ satisfying $r_0 = t^\gamma \leq \min\{r, \text{dist}(x, \partial\Omega)\}$,*

$$\mathbb{E}[K_t(x, X)] \geq \left(1 - \frac{2Kr_0}{p(x)}\right) (1 - Mr_0^2) e^{-L^2 r_0^4/t} p(x) \pi^{d/2} t^{d/2} - \tau(t)$$

and

$$\mathbb{E}[K_t(x, X)] \leq \left(1 + \frac{2Kr_0}{p(x)}\right) (1 + Mr_0^2) p(x) \pi^{d/2} t^{d/2} + \tau(t),$$

where $\tau(t) = e^{-r_0^2/t}$.

Remark 3.6. Let us note here that an optimal choice of γ depends on the size of L and M . In our analysis, $\tau(t)$ is basically a tail term, and large γ implies small tail term, but larger potential error due to geometric error accumulation. We leave aside the question of optimal γ in this work. In the numerical experiments of Section 4, $\gamma = 0.26$ worked well.

To achieve more manageable expressions in our later bounds, we introduce an auxiliary variable $0 < \eta < 1/2$, which allows us to express our bounds in a more simple form. The price we pay for this is stricter conditions on t , meaning we force t to be smaller than absolutely necessary. This in turn will imply larger sample size requirements to get concentration.

We need the bounds to hold uniformly over several moments of K_t , which is equivalent to bounds of K_t over several values of t . In the following lemma, we formulate several conditions on t for such bounds to hold:

Lemma 3.7 (Multiplicative Bounds). *Assume the conditions of Lemma 3.5 and let $\eta \in (0, 1/2)$. Define*

$$A := -\log\left(\frac{\eta}{10} p(x) \pi^{d/2} 2^{-d/2}\right), \quad f(s) := As + \frac{d}{2(1-2\gamma)} s \log \frac{1}{s}, \quad s \in (0, 1].$$

Let

$$s_T = \begin{cases} 1, & \text{if } f(1) \leq \frac{1}{2}, \\ \text{the unique } s \in (0, 1) \text{ with } f(s) = \frac{1}{2}, & \text{if } f(1) > \frac{1}{2}, \end{cases}$$

and set

$$t_T := s_T^{\frac{1}{1-2\gamma}}.$$

Define

$$\begin{aligned} t_0(\eta, L, M, K, \gamma, d, p) \\ = \min \left\{ \left(\frac{\eta}{10M}\right)^{\frac{1}{2\gamma}}, \left(\frac{-\log(1-\eta/10)}{2L^2}\right)^{\frac{1}{4\gamma-1}}, t_T, \left(\frac{p(x)\eta}{20K}\right)^{\frac{1}{\gamma-1}} \right\}. \end{aligned}$$

Then for any $t \leq t_0$ and $\hat{t} \in \mathcal{H} = \{t, t/2, 2t, 2t/3\}$,

$$(3.9) \quad (1-\eta) p(x) \pi^{d/2} \hat{t}^{d/2} \leq \mathbb{E}[K_{\hat{t}}(x, X)] \leq (1+\eta) p(x) \pi^{d/2} \hat{t}^{d/2}.$$

Remark 3.8. The threshold t_0 represents the largest bandwidth for which geometric distortions (curvature, volume distortion, density variation) remain sufficiently controlled. The function $f(s)$ and its root s_T arise from the trade-off between tail decay and geometric error accumulation. In practice, t_0 can be computed numerically via bisection on $f(s) = 1/2$.

Then we have the following simple corollary which gives us the necessary control on $\mathbb{E}[W^\pm]$ and $\text{Var}(W^\pm)$. Before stating the result, let us for convenience define

$$(3.10) \quad P_t := 2^{d/2} p(x) \pi^{d/2} t^{d/2} \approx \mathbb{E}[K_{2t}(x, X)],$$

which represents the expected kernel sum at bandwidth $2t$ under ideal geometric conditions. Then we have

Corollary 3.9 (Properties of W^+ and W^-). *Assume the conditions of Lemma 3.7. Further, let $0 < c < 1$ and $\eta = c \frac{2^{\varepsilon/2} - 1}{1 + 2^{\varepsilon/2}}$. Then*

$$\begin{aligned}\mathbb{E}[W^+] &\leq (1 - c)(1 - 2^{\varepsilon/2})P_t < 0 \\ \mathbb{E}[W^-] &\geq (1 - c)(1 - 2^{-\varepsilon/2})P_t > 0\end{aligned}$$

Furthermore,

$$\begin{aligned}\text{Var}(W^+) &\leq 2^{\varepsilon+3}P_t \\ \text{Var}(W^-) &\leq 2^{-\varepsilon+3}P_t.\end{aligned}$$

Remark 3.10. The condition on η ensures $\mathbb{E}[W^\pm]$ have the correct sign with sufficient margin (controlled by c) to apply Bernstein's inequality effectively. Smaller c gives tighter conditions on t but stronger concentration once satisfied.

Now we can state and prove the main result of this section:

Theorem 2 (Concentration of Dimension Estimator). *Under the conditions of Lemma 3.7 and Corollary 3.9, we have*

$$\mathbb{P}(\hat{d} - d \geq \varepsilon) \leq \exp\left(\frac{-nc_+^2 P_t}{2^{4+\varepsilon} + \frac{2}{3}M_{d,\varepsilon}c_+}\right)$$

and

$$\mathbb{P}(\hat{d} - d \leq -\varepsilon) \leq \exp\left(\frac{-nc_-^2 P_t}{2^{4-\varepsilon} + \frac{2}{3}M_{d,-\varepsilon}c_-}\right),$$

where $M_{d,\pm\varepsilon} = 1 + 2^{(d\pm\varepsilon)/2}$, $c_+ = (1 - c)(2^{\varepsilon/2} - 1)$ and $c_- = (1 - c)(1 - 2^{-\varepsilon/2})$.

Using Corollary 3.9, the proof of Theorem 2 is straightforward:

Proof of Theorem 2. First we recall the decompositions (3.4) and (3.5) and variables (3.6) and (3.7). Then we observe that

$$\begin{aligned}-2^{(d+\varepsilon)/2} &\leq K_{2t}(x, X) - 2^{(d+\varepsilon)/2}K_t(x, X) \leq 1, \\ -2^{(d-\varepsilon)/2} &\leq K_{2t}(x, X) - 2^{(d-\varepsilon)/2}K_t(x, X) \leq 1,\end{aligned}$$

and thus $|W^\pm - \mathbb{E}[W^\pm]| \leq 1 + 2^{(d\pm\varepsilon)/2} = M_{d,\pm\varepsilon}$.

Using our estimates from Corollary 3.9, a direct application of Bernstein's inequality to (3.4) gives

$$\begin{aligned}\mathbb{P}(\hat{d} - d \geq \varepsilon) &\leq \exp\left(\frac{-n(c_+P_t)^2}{2(2^{\varepsilon+3}P_t + M_{d,\varepsilon}(c_+P_t)/3)}\right) \\ &= \exp\left(\frac{-nc_+^2 P_t}{2^{4+\varepsilon} + \frac{2}{3}M_{d,\varepsilon}c_+}\right),\end{aligned}$$

and similarly for $-\varepsilon$ in (3.5),

$$\begin{aligned}\mathbb{P}(\hat{d} - d \leq -\varepsilon) &\leq \exp\left(\frac{-n(c_-P_t)^2}{2(2^{-\varepsilon+3}P_t + M_{d,-\varepsilon}(c_-P_t)/3)}\right) \\ &= \exp\left(\frac{-nc_-^2 P_t}{2^{4-\varepsilon} + \frac{2}{3}M_{d,-\varepsilon}c_-}\right).\end{aligned}$$

□

Remark 3.11 (Practical considerations). Some practical considerations:

- **Unknown geometric parameters:** Computing t_0 of Lemma 3.7 requires knowing $L, M, K, p(x)$. In practice, these must be estimated from data or conservatively bounded. Our contribution is showing *how* geometry is affected by these parameters.

- **Dimension assumption:** To apply these bounds, one needs an upper bound on d (to ensure $t \leq t_0$). This has to be obtained from initial estimates or domain knowledge. A trivial upper bound is ambient dimension N .
- **Confidence intervals:** With estimated geometric parameters, the bounds enable finite-sample confidence interval construction, which existing asymptotic results do not provide.

3.2. Anti-concentration. Theorem 2 provides an upper bound on the probability that \hat{d} deviates from d . In this section we prove a complementary result that establishes when our estimator *cannot* reliably distinguish d from nearby values. Specifically, we seek an upper bound on

$$(3.11) \quad \mathbb{P}(|\hat{d} - d| \leq \varepsilon).$$

We work with the same theoretical setup and assumptions made on Ω, X_1, \dots, X_n and p as in Section 3.1. While dimension estimators are often applied to data with non-integer (fractional) dimensions, our anti-concentration analysis requires integer d . This is because our proofs rely on manifold structure; they specifically require integration over the d -dimensional tangent space $T_x \Omega \cong \mathbb{R}^d$.

In order to bound (3.11), we use normal approximation through the Berry-Esseen theorem:

Theorem 3 (Berry–Esseen, i.i.d. with explicit constant). *Let X_1, X_2, \dots be i.i.d. with mean μ , variance $\sigma^2 > 0$, and*

$$\rho := \mathbb{E}|X_1 - \mu|^3 < \infty.$$

Define $S_n = \frac{1}{n} \sum_{i=1}^n X_i$ and

$$F_n(x) := \mathbb{P}\left(\frac{\sqrt{n}S_n - \sqrt{n}\mu}{\sigma} \leq x\right), \quad \Phi(x) := \frac{1}{\sqrt{2\pi}} \int_{-\infty}^x e^{-t^2/2} dt.$$

Then

$$\sup_{x \in \mathbb{R}} |F_n(x) - \Phi(x)| \leq C \frac{\rho}{\sigma^3 \sqrt{n}}, \quad C \leq 0.4748.$$

Similarly to the proof of Theorem 2, the main work consists in finding bounds on μ, σ and ρ of appropriate random variables.

First we rewrite $\mathbb{P}(|\hat{d} - d| \leq \varepsilon)$,

$$(3.12) \quad \begin{aligned} \mathbb{P}(|\hat{d} - d| \leq \varepsilon) &= \mathbb{P}\left(\left|\frac{2}{\log(2)} \log\left(\frac{S(x, 2t)}{S(x, t)}\right) - d\right| \leq \varepsilon\right) \\ &= \mathbb{P}\left(\frac{S(x, 2t)}{S(x, t)} \in [2^{d/2-\varepsilon/2}, 2^{d/2+\varepsilon/2}]\right) \\ &= \mathbb{P}\left(\frac{S(x, 2t)}{S(x, t)} \geq 2^{d/2-\varepsilon/2}\right) - \mathbb{P}\left(\frac{S(x, 2t)}{S(x, t)} \geq 2^{d/2+\varepsilon/2}\right) \\ &= \mathbb{P}\left(\frac{S(x, 2t)}{S(x, t)} \geq 2^{d/2-\varepsilon/2}\right) - \left(1 - \mathbb{P}\left(\frac{S(x, 2t)}{S(x, t)} \leq 2^{d/2+\varepsilon/2}\right)\right) \\ &= \mathbb{P}\left(2^{(d-\varepsilon)/2} S(x, t) - S(x, 2t) \leq 0\right) \\ &\quad + \mathbb{P}\left(2^{(d+\varepsilon)/2} S(x, t) - S(x, 2t) \geq 0\right) - 1. \end{aligned}$$

Similar to the previous section, we need to understand the random variables

$$(3.13) \quad \begin{aligned} Y_+ &= 2^{(d+\varepsilon)/2} K_t(x, X) - K_{2t}(x, X) \\ Y_- &= 2^{(d-\varepsilon)/2} K_t(x, X) - K_{2t}(x, X), \end{aligned}$$

where $X \sim p$. To prove the main theorem of this section, the strategy is to use normal approximation on the decomposition (3.12), and to do this we need bounds on μ, σ^2 and ρ for the random variables above, Y_+, Y_- .

Lemma 3.12. *Let Y_+, Y_- be as in (3.13). Define*

$$\begin{aligned}\Gamma_{\pm} &= 1 - 2^{1 \mp \varepsilon/2} \left(\frac{2}{3}\right)^{d/2} + 2^{-d/2 \mp \varepsilon}, \\ \Delta_{\pm} &= \left(\frac{2}{3}\right)^{d/2} + 3 \cdot 2^{\mp \varepsilon/2} 5^{-d/2} + 3 \cdot 2^{\mp \varepsilon - d/2} + 2^{\mp 3\varepsilon/2 - d/2} 3^{-d/2}.\end{aligned}$$

Assume $\Gamma_+ > 0$ and let $c \in (0, 1)$ satisfy

$$(3.14) \quad \eta := c \frac{2^{\varepsilon/2} - 1}{1 + 2^{\varepsilon/2}} < \frac{\Gamma_+}{1 + 2^{1-\varepsilon/2} (2/3)^{d/2} + 2^{-d/2-\varepsilon}}.$$

Define $\eta_{\pm}^* = \eta \frac{1 + 2^{1 \mp \varepsilon/2} (2/3)^{d/2} + 2^{-d/2 \mp \varepsilon}}{\Gamma_{\pm}}$.

Then, for t sufficiently small:

$$\begin{aligned}\mathbb{E}[Y_+] &\leq (2^{\varepsilon/2} - 1)(1 + c)P_t, \\ \mathbb{E}[-Y_-] &\leq (1 - 2^{-\varepsilon/2})(1 + c)P_t, \\ \text{Var}(Y_{\pm}) &\geq 2^{\pm \varepsilon} \Gamma_{\pm} (1 - \eta_{\pm}^*) P_t + \mathcal{O}(P_t^2), \\ \mathbb{E}[|Y_{\pm} - \mathbb{E}[Y_{\pm}]|^3] &\leq (1 + \eta) \Delta_{\pm} 2^{d/2 \pm 3\varepsilon/2} P_t + \mathcal{O}(P_t^2).\end{aligned}$$

The condition on η ensures $\eta_{\pm}^* < 1$.

Remark 3.13. The condition “ t sufficiently small” means the multiplicative bounds of Lemma 3.7 hold for the extended set $\hat{t} \in \{t/3, 2t/5, t/2, 2t/3, t, 2t\}$. The third moment bounds require $K_t^3 = K_{t/3}$ and $K_t^2 K_{2t} = K_{2t/5}$, which are not in the original set \mathcal{H} . This will potentially yield a slightly smaller threshold t_0 than in Lemma 3.7.

Now we have all the bounds we need, and can apply Berry-Esseen:

Corollary 3.14 (Berry-Esseen bound). *Define $Y_{i,\pm} = 2^{(d \pm \varepsilon)/2} K_t(x, X_i) - K_{2t}(x, X_i)$ for $i = 1, \dots, n$. Under the assumptions of Lemma 3.12,*

$$\begin{aligned}\sup_{x \in \mathbb{R}} \left| \mathbb{P} \left(\frac{\sum_{i=1}^n (Y_{i,\pm} - \mathbb{E}[Y_{i,\pm}])}{\sqrt{n \text{Var}(Y_{i,\pm})}} \leq x \right) - \Phi(x) \right| &\leq \frac{C(1 + \eta) \Delta_{\pm} 2^{d/2}}{\sqrt{n} \sqrt{P_t} (1 - \eta_{\pm}^*)^{3/2} \Gamma_{\pm}^{3/2}} \\ &\quad + \mathcal{O} \left(\sqrt{\frac{P_t}{n}} \right)\end{aligned}$$

where $C \leq 0.4748$ is the Berry-Esseen constant.

Now we are ready to state the main result on anti-concentration, which follows easily from Corollary 3.14:

Theorem 4 (Anti-concentration for Gaussian Kernel Estimator). *Let $\Phi(x)$ be the CDF of the standard normal distribution and $\varepsilon > 0$. Under the conditions of Lemma 3.12, we have*

$$(3.15) \quad \begin{aligned}\mathbb{P}(|\hat{d}(x, t) - d| \leq \varepsilon) &\leq \Phi \left(\frac{(2^{\varepsilon/2} - 1)(1 + c) \sqrt{P_t n}}{2^{\varepsilon/2} \sqrt{\Gamma_+ (1 - \eta_+^*)}} \right) \\ &\quad + \Phi \left(\frac{(1 - 2^{-\varepsilon/2})(1 + c) \sqrt{P_t n}}{2^{-\varepsilon/2} \sqrt{\Gamma_- (1 - \eta_-^*)}} \right) \\ &\quad + \frac{C(1 + \eta) 2^{d/2}}{\sqrt{P_t n}} \left(\frac{\Delta_+}{(1 - \eta_+^*)^{3/2} \Gamma_+^{3/2}} + \frac{\Delta_-}{(1 - \eta_-^*)^{3/2} \Gamma_-^{3/2}} \right) + \mathcal{O} \left(\sqrt{\frac{P_t}{n}} \right) - 1\end{aligned}$$

where $C \leq 0.4748$ is the Berry-Esseen constant, $c, \eta, \Gamma_{\pm}, \eta_{\pm}^*, \Delta_{\pm}$ are as defined in Lemma 3.12, and P_t is defined in (3.10).

Proof. As in Corollary 3.14, define $Y_{-,i} = 2^{(d-\varepsilon)/2} K_t(x, X_i) - K_{2t}(x, X_i)$ with variance $\sigma_-^2 = \text{Var}(Y_{-,i})$. From Lemma 3.12, we have

$$\sigma_-^2 = \text{Var}(Y_-) \geq 2^{-\varepsilon} \Gamma_- (1 - \eta_-^*) P_t + O(P_t^2),$$

so $\sigma_- = 2^{-\varepsilon/2} \sqrt{\Gamma_- (1 - \eta_-^*) P_t} (1 + O(P_t))$.

Then beginning with the first term of decomposition in (3.12) and applying Corollary 3.14, we have

$$\begin{aligned} \mathbb{P}\left(2^{(d-\varepsilon)/2} S(x, t) - S(x, 2t) \leq 0\right) &= \mathbb{P}\left(\frac{1}{\sqrt{n}} \sum_{i=1}^n \frac{Y_{-,i} - \mathbb{E}[Y_{-,i}]}{\sigma_-} \leq -\frac{\sqrt{n} \mathbb{E}[Y_{-,i}]}{\sigma_-}\right) \\ &\leq \Phi\left(\frac{\sqrt{n} \mathbb{E}[-Y_{-,i}]}{\sigma_-}\right) + \frac{C \rho_-}{\sigma_-^3 \sqrt{n}} \\ &\leq \Phi\left(\frac{\sqrt{n} \cdot (1 - 2^{-\varepsilon/2})(1+c) P_t}{2^{-\varepsilon/2} \sqrt{\Gamma_- (1 - \eta_-^*) P_t} (1 + O(P_t))}\right) \\ &\quad + \frac{C(1+\eta) \Delta_- 2^{d/2}}{(1 - \eta_-^*)^3 \Gamma_-^{3/2}} \frac{1}{\sqrt{n P_t}} + O\left(\sqrt{\frac{P_t}{n}}\right) \\ &= \Phi\left(\frac{(1 - 2^{-\varepsilon/2})(1+c) \sqrt{P_t n}}{2^{-\varepsilon/2} \sqrt{\Gamma_- (1 - \eta_-^*)}}\right) \\ &\quad + \frac{C(1+\eta) \Delta_- 2^{d/2}}{(1 - \eta_-^*)^3 \Gamma_-^{3/2}} \frac{1}{\sqrt{n P_t}} + O\left(\sqrt{\frac{P_t}{n}}\right). \end{aligned}$$

Similarly, let $Y_{+,i} = 2^{(d+\varepsilon)/2} K_t(x, X_i) - K_{2t}(x, X_i)$ with variance $\sigma_+^2 = \text{Var}(Y_{+,i})$. From Lemma 3.12,

$$\sigma_+^2 = \text{Var}(Y_+) \geq 2^{\varepsilon} \Gamma_+ (1 - \eta_+^*) P_t + O(P_t^2),$$

so $\sigma_+ = 2^{\varepsilon/2} \sqrt{\Gamma_+ (1 - \eta_+^*) P_t} (1 + O(P_t))$. Then for the second term of (3.12),

$$\begin{aligned} \mathbb{P}\left(2^{(d+\varepsilon)/2} S(x, t) - S(x, 2t) \geq 0\right) &= \mathbb{P}\left(\frac{1}{\sqrt{n}} \sum_{i=1}^n \frac{Y_{+,i} - \mathbb{E}[Y_{+,i}]}{\sigma_+} \geq -\frac{\sqrt{n} \mathbb{E}[Y_{+,i}]}{\sigma_+}\right) \\ &= 1 - \Phi\left(-\frac{\sqrt{n} \mathbb{E}[Y_{+,i}]}{\sigma_+}\right) + \frac{C \rho_+}{\sigma_+^3 \sqrt{n}} \\ &= \Phi\left(\frac{\sqrt{n} \mathbb{E}[Y_{+,i}]}{\sigma_+}\right) + \frac{C \rho_+}{\sigma_+^3 \sqrt{n}} \\ &\leq \Phi\left(\frac{\sqrt{n} \cdot (2^{\varepsilon/2} - 1)(1+c) P_t}{2^{\varepsilon/2} \sqrt{\Gamma_+ (1 - \eta_+^*) P_t} (1 + O(P_t))}\right) \\ &\quad + \frac{C(1+\eta) \Delta_+ 2^{d/2}}{(1 - \eta_+^*)^3 \Gamma_+^{3/2}} \frac{1}{\sqrt{n P_t}} + O\left(\sqrt{\frac{P_t}{n}}\right) \\ &= \Phi\left(\frac{(2^{\varepsilon/2} - 1)(1+c) \sqrt{P_t n}}{2^{\varepsilon/2} \sqrt{\Gamma_+ (1 - \eta_+^*)}}\right) \\ &\quad + \frac{C(1+\eta) \Delta_+ 2^{d/2}}{(1 - \eta_+^*)^3 \Gamma_+^{3/2}} \frac{1}{\sqrt{n P_t}} + O\left(\sqrt{\frac{P_t}{n}}\right). \end{aligned}$$

Combining both bounds:

$$\begin{aligned} \mathbb{P}(|\hat{d}(x, t) - d| \leq \varepsilon) &\leq \Phi\left(\frac{(2^{\varepsilon/2} - 1)(1 + c)\sqrt{P_t n}}{2^{\varepsilon/2}\sqrt{\Gamma_+(1 - \eta_+^*)}}\right) \\ &\quad + \Phi\left(\frac{(1 - 2^{-\varepsilon/2})(1 + c)\sqrt{P_t n}}{2^{-\varepsilon/2}\sqrt{\Gamma_-(1 - \eta_-^*)}}\right) \\ &\quad + \frac{C(1 + \eta)2^{d/2}}{\sqrt{P_t n}} \left(\frac{\Delta_+}{(1 - \eta_+^*)^{3/2}\Gamma_+^{3/2}} + \frac{\Delta_-}{(1 - \eta_-^*)^{3/2}\Gamma_-^{3/2}} \right) \\ &\quad + O\left(\sqrt{\frac{P_t}{n}}\right) - 1. \end{aligned}$$

□

From our results, we can note a few different regimes for ε . First, to have informative bounds, we always need $\sqrt{P_t n} \gg 1$ in order for the error terms to be negligible. Then, in addition, if $\varepsilon \ll 1/\sqrt{nP_t}$, the bound approaches zero, indicating we cannot expect \hat{d} within ε of d . When $\varepsilon \sim 1/\sqrt{nP_t}$, this represents the finest achievable resolution with n samples. For $\varepsilon \gg 1/\sqrt{nP_t}$, the bound saturates near 1 and becomes uninformative.

Remark 3.15. Since we require $\sqrt{P_t n} \gg 1$ for the bound to be meaningful, the term $O(\sqrt{P_t/n})$ will be very small. Proofs can be adjusted to obtain explicit constants for this term as well, but for ease of presentation we leave it in O notation.

The following remark makes the small- ε scaling more explicit.

Remark 3.16 (Small- ε behavior). In the regime where ε is small and $P_t n$ is large with $\varepsilon\sqrt{P_t n} \lesssim 1$, the bound in Theorem 4 simplifies. The Φ terms can be expanded as $\Phi(x) \approx \frac{1}{2} + \frac{x}{\sqrt{2\pi}}$ for small arguments, and the constants $\Gamma_{\pm}, \eta_{\pm}^*$ approach their $\varepsilon = 0$ limits:

$$\Gamma_0 = 1 - 2\left(\frac{2}{3}\right)^{d/2} + 2^{-d/2}, \quad \eta_0^* = \eta \frac{1 + 2(2/3)^{d/2} + 2^{-d/2}}{\Gamma_0}.$$

The leading-order behavior becomes

$$\mathbb{P}(|\hat{d}(x, t) - d| \leq \varepsilon) \approx \frac{\log 2}{\sqrt{2\pi}\Gamma_0(1 - \eta_0^*)} (1 + c)\sqrt{P_t n} \varepsilon.$$

3.3. A bandwidth selection heuristic. As noted in [7], to estimate the dimension we need to identify regions where the correct kernel statistics apply, where the kernel sum (3.1) grows proportionally to $t^{d/2}$. Fig. 3 illustrates this scaling behavior numerically for the Gaussian kernel.

The bandwidth selection method in [7] relied on visual inspection of log-log plots to find the most linear region, which [6] automated via *slope maximization* over a dyadic scale. We seek to improve upon this automatic selection criterion.

In many cases, slope maximization works well. However, even in the simple example of Fig. 3, the maximal slope slightly overestimates the dimension. While the correct scaling regime lies near the maximal slope, the estimate is more stable within (rather than at the boundary of) this regime.

One advantage of the Gaussian kernel over indicator kernels is smoothness: derivatives of the kernel sum are well-defined and can be computed efficiently (Proposition B.1). This motivates exploring whether derivative information can improve bandwidth selection—an approach unavailable for discontinuous kernels such as the indicator kernel.

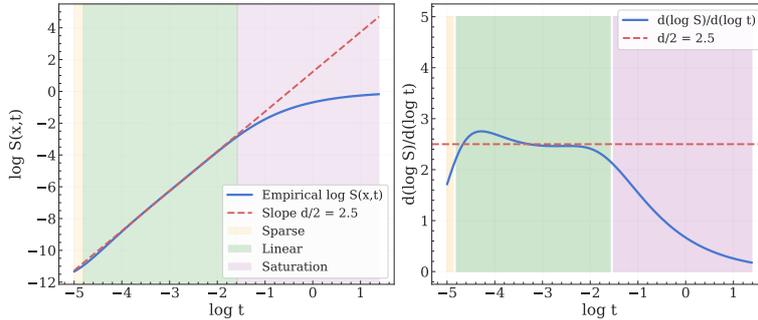

FIGURE 3. Scaling regimes of the kernel sum for unit ball in \mathbb{R}^5 with $n = 100,000$ samples. Left: log-log plot showing linear regime with slope $d/2$. Right: derivative plateau indicating the linear regime.

We suggest utilizing more information in the derivatives of $\log S(x, t)$ to better capture the linear scaling region.

While a complete theoretical analysis of optimal bandwidth selection is beyond our scope, we propose a simple heuristic that sometimes improves over slope maximization. If we define $G(t) := \log S(x, e^t)$, the heuristic is to maximize $\rho(t) = G'(t)/(|G''(t)| + \delta)$, which balances large slope with stability. Here δ is a small constant to avoid division by zero. This method leverages the smooth Gaussian kernel's derivative structure (Proposition B.1). The complete algorithm is summarized in Algorithm 1, found in Section B. In Section 4 we provide some numerical comparisons between this method and slope maximization.

Remark 3.17. We emphasize that Algorithm 1 is a heuristic without theoretical guarantees. We include it as: (i) motivation for working with smooth kernels where derivatives are available, and (ii) demonstration that derivative information can sometimes improve over slope maximization. A complete theoretical analysis is left for future work.

4. NUMERICAL EXPERIMENTS

Having established our theoretical bounds, we now validate them numerically by comparing our bounds to empirical performance. We begin by applying our theoretical results Theorems 2 and 4 to specific manifolds where we can calculate all necessary parameters.

After this we test our proposed bandwidth selection from Section 3.3, by comparing our estimator against the maximization method of [6]. We include the indicator kernel approach in our comparisons to provide a baseline.

4.1. Concentration experiments. We test our theoretical results in Theorem 2 against two manifolds, a three-dimensional ball and three-dimensional spherical cap. We compare the empirical concentration of these two manifolds against the concentration given by Theorem 2. The manifold parameters L, M, r of the spherical cap are calculated similarly to Example 3.3.

In line with theory, in Fig. 4 our theoretical bounds successfully bound the empirical error, though with considerable slack (approximately 2 orders of magnitude). While the bounds are conservative, the slopes suggest our bounds are proportional to the correct scaling with respect to n .

In Fig. 5 we have compared our theoretical anti-concentration bounds to the empirical ones for the three-dimensional spherical cap. In Fig. 5a we show the

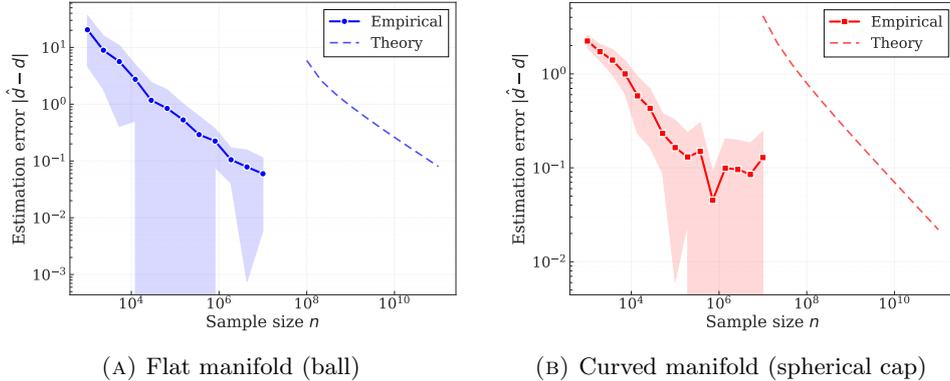

FIGURE 4. Concentration of dimension estimation error for intrinsic dimension $d = 3$. Panel (a) shows a uniform distribution on the unit ball in \mathbb{R}^3 (flat geometry) with bandwidth $t = 0.000555 < t_0 = 0.000585$. Panel (b) shows an approximately uniform distribution on a spherical cap of a 3-sphere with radius $R = 10$ and bandwidth $t = 0.000768 < t_0 = 0.000808$. Solid lines represent empirical mean errors, dashed lines show theoretical concentration bounds at 90% confidence, and shaded regions indicate standard deviation.

linear scaling of Remark 3.16, showing the accuracy limit for our estimator. For a given n , we cannot expect \hat{d} to distinguish d from nearby values within tolerance c^* .

In Fig. 5c we calculate our exact theoretical bounds for different values of n and tolerances, which can be compared to empirical estimates in Fig. 5b. As in the concentration plots, we can note that empirically, the plots are much better than the worst case predicted by Theorem 4.

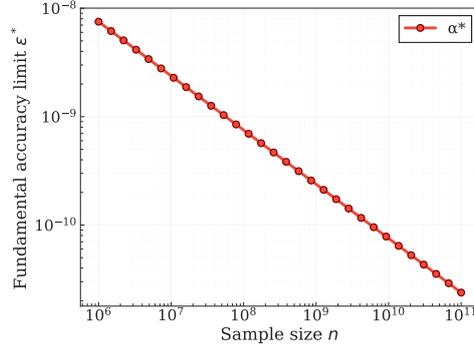

4.2. Bandwidth selection experiments. In this section we compare our bandwidth selection heuristic in Algorithm 1 to slope maximization, as well as the indicator kernel approach. Since noise is common in many applications, we add i.i.d. (ambient dimensional) Gaussian noise $\mathcal{N}(0, \sigma^2 I_N)$ to each of our samples before estimating dimension, for noise levels $\sigma \in \{0.0, 0.15, 0.30, 0.50\}$, and vary the number of samples. Each manifold is tested with a fixed reference point. The results are summarized in Fig. 7 and Fig. 6.

We also extend our comparisons to the manifolds in the standard benchmark suggested in [19]. However, we restrict our comparison to datasets with intrinsic dimension less than 10. This is because generally this class of estimators (more or less volume-based) do not perform well in higher dimensions, and comparisons are not interesting there. See Fig. 8 for a summary of this restricted benchmark.

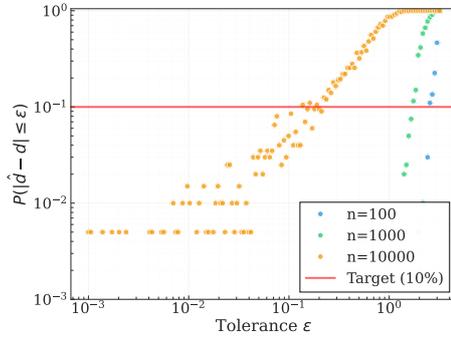

These results show neither kernel nor bandwidth selection consistently outperforming others in all cases, but our proposed method overall seems to outperform the alternatives in this limited comparison.

5. CONCLUSION AND FUTURE WORK

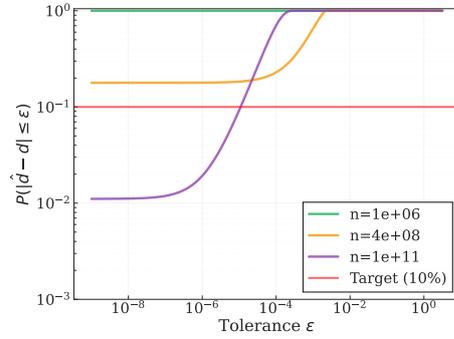

We characterized concentration and anti-concentration properties of Gaussian kernel dimension estimators with explicit dependence on sample size, bandwidth, and geometrical/distributional regularity parameters. Our theoretical bound in

(A) Critical threshold ε^* versus sample size n from Remark 3.16. Below ε^* , the upper bound on $\mathbb{P}(|\hat{d} - d| \leq \varepsilon)$ is at most 0.1.

(B) Empirical probabilities $\mathbb{P}(|\hat{d} - d| \leq \varepsilon)$ over 200 trials for $n \in \{100, 1000, 10000\}$. Red line: target threshold 0.1.

(C) Theoretical bounds from Theorem 4 for $n \in \{10^6, 10^8, 10^{11}\}$.

FIGURE 5. Anti-concentration bounds on spherical cap.

Experiments on a spherical cap of a 3-sphere with radius $R = 10$ (intrinsic dimension $d = 3$, $L = 0.05$, $M = 0.005$) with bandwidth $t = 0.000768 < t_0 = 0.000808$. The anti-concentration bounds show fundamental accuracy limits.

Theorem 2 provides a basis for rigorous confidence intervals, Theorem 4 demonstrates the inherent limits of precision for this estimator, and our bandwidth heuristic (Algorithm 1) leverages derivative information to improve practical performance.

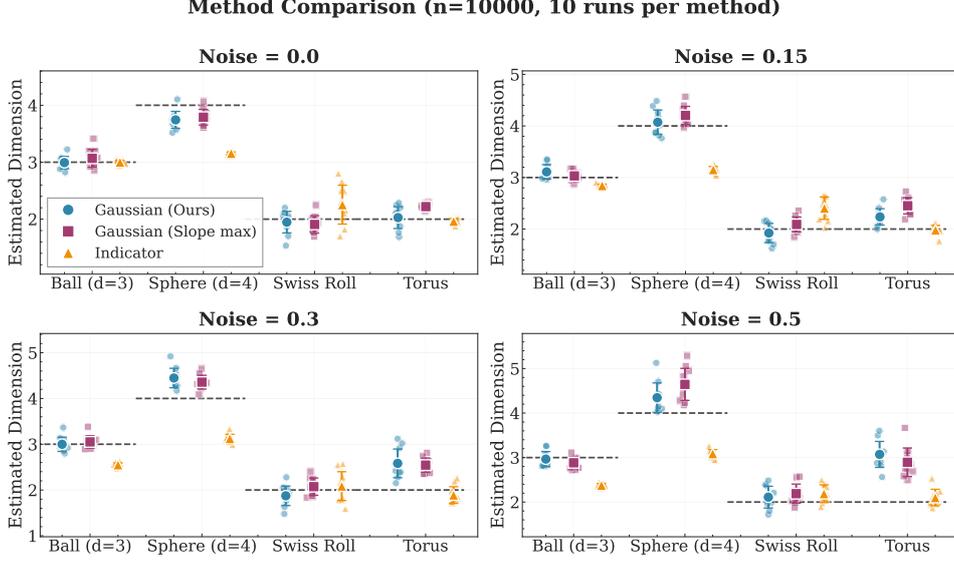

FIGURE 6. Distribution of estimated intrinsic dimension at noise levels $\sigma \in \{0.0, 0.15, 0.30, 0.50\}$ for the largest sample size ($n = 10^4$). Each violin aggregates 10 runs on four manifolds (Ball $d = 3$, Sphere $d = 4$, Swiss Roll $d = 2$, Torus $d = 2$), showing Gaussian (Ours), Gaussian (Slope max), and indicator kernels side by side; the dashed line marks the true dimension.

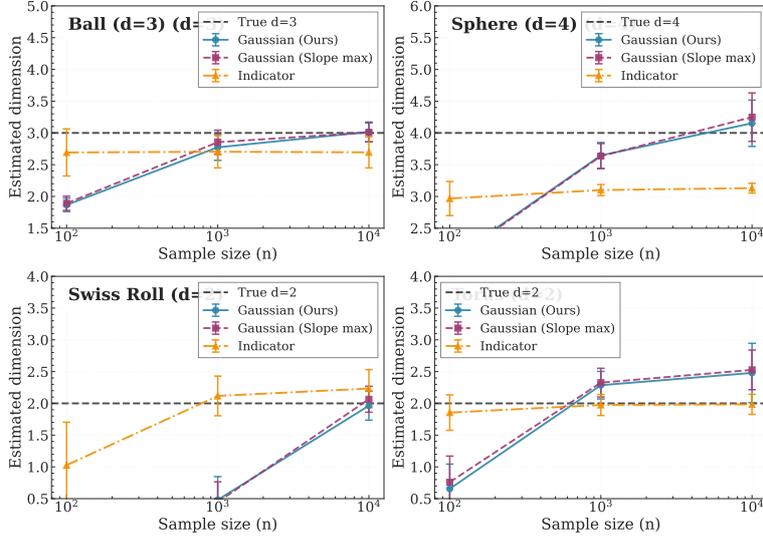

FIGURE 7. Gaussian (Ours) (blue), Gaussian (Slope max) (purple), and indicator kernel (orange) dimension estimates versus sample size ($n \in \{100, 1000, 10,000\}$) for Ball ($d = 3$), Sphere ($d = 4$), Swiss Roll ($d = 2$), and Torus ($d = 2$). Curves average 10 runs across all noise levels ($\sigma \in \{0.0, 0.15, 0.30, 0.50\}$), with error bars showing one standard deviation, and dashed lines marking the true intrinsic dimensions.

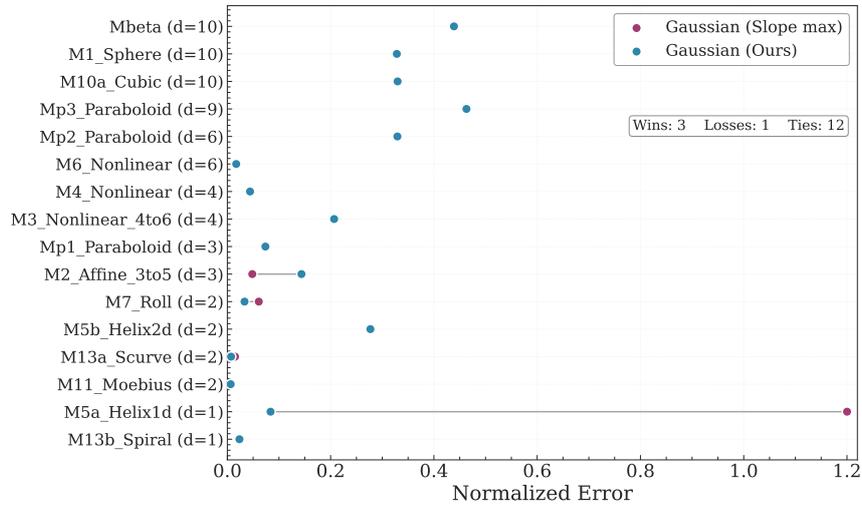

FIGURE 8. Normalized error $|\hat{d} - d|/d$ for Gaussian (Slope max) (purple) and Gaussian (Ours) (blue) across the scikit-dimension manifolds with intrinsic dimension $d \leq 10$ ($n = 10,000$ samples, 10 runs per method, no ambient noise). Gray connectors link paired estimates; the inset reports how often our method wins, loses, or ties.

Limitations and Future Directions:

- **Loose bounds:** Concentration bounds overestimate errors by $\sim 100\times$ (Figure 4), due to multiplicative slack for analytical tractability and worst-case analysis over all manifolds with given (L, M, r, p) . Tighter bounds may be achievable through refined analysis or alternative proof techniques.
- **Unknown constants:** Bounds depend on $L, M, r, p(x), K$, which must be estimated from data.
- **Integer dimension assumption:** Anti-concentration proofs assume $d \in \mathbb{N}$; extending to fractional dimensions remains open.
- **Bandwidth selection:** The heuristic (Algorithm 1) performs well empirically (Figs. 6–8) but lacks theoretical guarantees. Higher-order derivatives beyond G'' could enable automatic detection of scaling regime transitions.
- **Kernel choice:** Systematic analysis of alternative kernels (exponential, Cauchy) may reveal performance trade-offs for specific geometric conditions or noise models.

APPENDIX A. GAUSSIAN KERNEL PROOFS

A.1. **Proof of Lemma 3.5.** Since the manifold is locally (L, M, r) -regular at x , and $r_0 \leq r$, in the ball $B_r(x)$ we can use the projection π from Definition 3.1. Let $y \in B_{r_0}(x) \cap \Omega$, $z := \pi(y) - x \in T_x\Omega$ and $h_z := \pi(y) - y$. By (L, M, r) -regularity, we have that

$$(A.1) \quad \|x - y\|^2 = \|z\|^2 + \|h_z\|^2, \quad 0 \leq \|h_z\|^2 \leq L^2 \|z\|^4.$$

For the volume element of π^{-1} , $V(y)$, we have that

$$(A.2) \quad (1 - M\|z\|^2) \leq V(y) \leq (1 + M\|z\|^2),$$

and since p is K -Lipschitz, we know that

$$(A.3) \quad |p(x) - p(y)| \leq K\|x - y\| \leq K(\|z\| + \|h_z\|) \leq 2Kr_0.$$

To compute $\mathbb{E}[K_t(x, X)]$, we split the integration over $U := B_{r_0}(x) \cap \Omega$ and $U^c := \Omega \setminus B_{r_0}(x)$. For $y \in U^c$, $\|x - y\| \geq r_0$, since p is a density, we have that

$$\int_{U^c} K_t(x, y)p(y)dy \leq e^{-r_0^2/t} = \tau(t)$$

Then using (A.1)–(A.3) we get

$$\begin{aligned} \int_{\Omega} K_t(x, y)p(y)dy &\geq \int_U K_t(x, y)p(y)dy \geq \int_U e^{-(\|z\|^2 + L^2\|z\|^4)/t} p(y)dy \\ &\geq e^{-L^2r_0^4/t} \int_U e^{-\|z\|^2/t} p(y)dy \\ &= e^{-L^2r_0^4/t} \int_{\mathbb{R}^d} e^{-\|z\|^2/t} p(\pi^{-1}(z))V(y(z))dz \\ &\quad - e^{-L^2r_0^4/t} \int_{\|z\| \geq r_0} e^{-\|z\|^2/t} p(\pi^{-1}(z))V(y(z))dz \\ &\geq (p(x) - 2Kr_0)(1 - Mr_0^2)e^{-L^2r_0^4/t} \pi^{d/2} t^{d/2} - \tau(t) \\ &= \left(1 - \frac{2Kr_0}{p(x)}\right) (1 - Mr_0^2) e^{-L^2r_0^4/t} p(x) \pi^{d/2} t^{d/2} - \tau(t) \end{aligned} \tag{A.4}$$

Similarly, for an upper bound we get

$$\begin{aligned} \int_{\Omega} K_t(x, y)p(y)dy &\leq \int_U K_t(x, y)p(y)dy + \tau(t) \\ &\leq (p(x) + 2Kr_0) \int_{\|z\| \leq r_0} e^{-(\|z\|^2)/t} (1 + M\|z\|^2) dz + \tau(t) \\ &\leq (p(x) + 2Kr_0)(1 + Mr_0^2) \int_{\mathbb{R}^d} e^{-\|z\|^2/t} dz + \tau(t) \\ &\leq (p(x) + 2Kr_0)(1 + Mr_0^2) \pi^{d/2} t^{d/2} + \tau(t) \\ &= \left(1 + \frac{2Kr_0}{p(x)}\right) (1 + Mr_0^2) p(x) \pi^{d/2} t^{d/2} + \tau(t) \end{aligned} \tag{A.5}$$

A.2. Proof of Lemma 3.7. From (A.4) and (A.5), to get multiplicative bounds as in (3.9) we need to control the factors

$$\left(1 - \frac{2Kr_0}{p(x)}\right) (1 - Mr_0^2) e^{-L^2r_0^4/\hat{t}} \left(1 - \frac{\tau(\hat{t})}{p(x) \pi^{d/2} \hat{t}^{d/2}}\right)$$

for the lower bound and

$$\left(1 + \frac{2Kr_0}{p(x)}\right) (1 + Mr_0^2) \left(1 + \frac{\tau(\hat{t})}{p(x) \pi^{d/2} \hat{t}^{d/2}}\right)$$

for the upper bound. Note that the exponential factor $e^{-L^2r_0^4/\hat{t}} \leq 1$ does not appear in the upper bound.

If each of the four factors in the lower bound is at least $1 - \eta/10$, and each of the three factors in the upper bound is at most $1 + \eta/10$, then since $(1 - \eta/10)^4 \geq 1 - \eta$ and $(1 + \eta/10)^3 \leq 1 + \eta$, the result follows.

Now what follows is getting uniform bounds of the above for $\hat{t} \in \mathcal{H}$, finding the largest t that satisfies them all. First we note that $r_0^2 = t^{2\gamma}$, and then note that

$$\max_{\hat{t} \in \mathcal{H}} \frac{L^2r_0^4}{\hat{t}} = \frac{L^2r_0^4}{t/2} = 2L^2t^{4\gamma-1}, \quad \max_{\hat{t} \in \mathcal{H}} e^{-\frac{r_0^2}{\hat{t}}} = e^{-\frac{r_0^2}{2t}} = e^{-\frac{1}{2}t^{2\gamma-1}}.$$

From this we arrive at the following sufficient conditions:

$$\begin{aligned}\frac{2Kt^\gamma}{p(x)} &\leq \frac{\eta}{10} \\ Mt^{2\gamma} &\leq \frac{\eta}{10} \\ 2L^2t^{4\gamma-1} &\leq -\log(1-\eta/10) \\ e^{-\frac{1}{2}t^{2\gamma-1}} &\leq \frac{\eta}{10}p(x)\pi^{d/2}\left(\frac{t}{2}\right)^{d/2}\end{aligned}$$

For clarity, we reformulate the last condition as follows:

$$\begin{aligned}e^{-\frac{1}{2}t^{2\gamma-1}} &\leq \frac{\eta}{10}p(x)\pi^{d/2}\left(\frac{1}{2}\right)^{d/2}t^{d/2} \\ -\frac{1}{2}t^{2\gamma-1} &\leq \log\left(\frac{\eta}{10}p(x)\pi^{d/2}2^{-d/2}\right) - \frac{d}{2}\log\frac{1}{t} \\ \frac{1}{2}t^{2\gamma-1} &\geq -\log\left(\frac{\eta}{10}p(x)\pi^{d/2}2^{-d/2}\right) + \frac{d}{2}\log\frac{1}{t}\end{aligned}$$

With $s := t^{1-2\gamma}$ and $A = -\log\left(\frac{\eta}{10}p(x)\pi^{d/2}2^{-d/2}\right)$, the above implies

$$\frac{1}{2s} \geq A + \frac{d}{2(1-2\gamma)} \log \frac{1}{s} \iff \frac{1}{2} \geq As + \frac{d}{2(1-2\gamma)} s \log \frac{1}{s}.$$

The expression on the right is concave in s over $[0, 1]$, which implies we can find a maximal s which satisfies the inequality.

A.3. Proof of Corollary 3.9. By Lemma 3.7

$$\begin{aligned}\mathbb{E}[W^+] &= \mathbb{E}[K_{2t}(x, X)] - 2^{(d+\varepsilon)/2}\mathbb{E}[K_t(x, X)] \\ &\leq (1+\eta)P_t - (1-\eta)2^{\varepsilon/2}P_t \\ &\leq (1+\eta-2^{\varepsilon/2}(1-\eta))P_t = (1-2^{\varepsilon/2}+\eta(1+2^{\varepsilon/2}))P_t \\ &\leq (1-c)(1-2^{\varepsilon/2})P_t.\end{aligned}$$

Similarly,

$$\begin{aligned}\mathbb{E}[W^-] &= \mathbb{E}[K_{2t}(x, X)] - 2^{(d-\varepsilon)/2}\mathbb{E}[K_t(x, X)] \\ &\geq (1-\eta)P_t - (1+\eta)2^{-\varepsilon/2}P_t \\ &\geq (1-\eta-2^{-\varepsilon/2}(1+\eta))P_t = (1-2^{-\varepsilon/2}-\eta(1+2^{-\varepsilon/2}))P_t \\ &\geq (1-c)(1-2^{-\varepsilon/2})P_t.\end{aligned}$$

For the variance, first we use that $\text{Var}(W) \leq \mathbb{E}[W^2]$. Then since $K_t^2 = K_{t/2}$, $K_{2t}^2 = K_t$, $K_t K_{2t} = K_{2t/3}$,

$$\begin{aligned}\text{Var}(W^+) &\leq \mathbb{E}[(W^+)^2] \leq \left(\mathbb{E}\left[K_{2t}^2 + 2^{(d+\varepsilon)/2+1}K_t K_{2t} + 2^{d+\varepsilon}K_t^2\right]\right) \\ &= \left(\mathbb{E}\left[K_t + 2^{(d+\varepsilon)/2+1}K_{2t/3} + 2^{d+\varepsilon}K_{t/2}\right]\right) \\ &\leq (1+\eta)\left(1 + 2^{(d+\varepsilon)/2+1}\left(\frac{2}{3}\right)^{d/2} + 2^{d/2+\varepsilon}\right)\pi^{d/2}t^{d/2}p(x) \\ &\leq (1+1/2)\left(2^{-d/2-\varepsilon} + 2^{-\varepsilon/2+1}\left(\frac{2}{3}\right)^{d/2} + 1\right)2^\varepsilon P_t \\ &\leq 2^{\varepsilon+3}P_t\end{aligned}$$

Similarly for W^- , but we have instead $\text{Var}(W^-) \leq 2^{-\varepsilon+3}P_t$.

A.4. **Proof of Lemma 3.12.** Throughout, we use the multiplicative bounds from Lemma 3.7, which hold for t sufficiently small.

First moment bounds. Using the definition of η and Lemma 3.7, direct calculation gives

$$(A.6) \quad \begin{aligned} \mathbb{E}[Y_+] &\leq ((1+\eta)2^{\varepsilon/2} - (1-\eta))P_t = (2^{\varepsilon/2} - 1 + \eta(2^{\varepsilon/2} + 1))P_t \\ &= (2^{\varepsilon/2} - 1)(1+c)P_t \end{aligned}$$

and

$$\begin{aligned} \mathbb{E}[-Y_-] &\leq ((1+\eta) - (1-\eta)2^{-\varepsilon/2})P_t = (1 - 2^{-\varepsilon/2} + \eta(2^{-\varepsilon/2} + 1))P_t \\ &= (1 - 2^{-\varepsilon/2})(1+c)P_t \end{aligned}$$

Variance bounds. Using (3.8),

$$(A.7) \quad \begin{aligned} \mathbb{E}[Y_+^2] &\geq \mathbb{E}\left[(1-\eta)2^{d+\varepsilon}K_{t/2} - (1+\eta)2^{(d+\varepsilon)/2+1}K_{2t/3} + (1-\eta)K_t\right] \\ &= ((1-\eta)(2^{d/2+\varepsilon} + 1) - (1+\eta)(2^{d+\varepsilon/2+1}3^{-d/2}))\pi^{d/2}t^{d/2}p(x) \\ &= ((2^{d/2+\varepsilon} - 2^{d+\varepsilon/2+1}3^{-d/2} + 1) - \eta(2^{d/2+\varepsilon} + 1 + 2^{d+\varepsilon/2+1}3^{-d/2}))\pi^{d/2}t^{d/2}p(x) \\ &= ((2^\varepsilon - 2^{d/2+\varepsilon/2+1}3^{-d/2} + 2^{-d/2}) - \eta(2^\varepsilon + 2^{d/2+\varepsilon/2+1}3^{-d/2} + 2^{-d/2}))P_t \\ &= 2^\varepsilon P_t \left(\left(1 - 2^{1-\varepsilon/2} \left(\frac{2}{3}\right)^{d/2} + 2^{-d/2-\varepsilon}\right) - \eta \left(1 + 2^{1-\varepsilon/2} \left(\frac{2}{3}\right)^{d/2} + 2^{-d/2-\varepsilon}\right) \right) \\ &= 2^\varepsilon \Gamma_+(1 - \eta_+^*)P_t, \end{aligned}$$

The condition $\eta_+^* < 1$ ensures this bound is positive. From (A.6)

$$\mathbb{E}[Y_+]^2 \leq ((2^{\varepsilon/2} - 1)(1+c)P_t)^2.$$

Then

$$\begin{aligned} \text{Var}(Y_+) &= \mathbb{E}[Y_+^2] - \mathbb{E}[Y_+]^2 \geq 2^\varepsilon \Gamma_+(1 - \eta_+^*)P_t - ((2^{\varepsilon/2} - 1)(1+c)P_t)^2 \\ &= 2^\varepsilon \Gamma_+(1 - \eta_+^*)P_t + \mathcal{O}(P_t^2) = C_\sigma P_t + \mathcal{O}(P_t^2), \end{aligned}$$

where $C_\sigma = 2^\varepsilon \Gamma_+(1 - \eta_+^*)$.

Third moment bounds. First we note that using (3.8), similar calculations as in (A.7) yield $\mathbb{E}[Y_+^m] = \mathcal{O}(P_t)$ and (A.6) gives $\mathbb{E}[Y_+]^m = \mathcal{O}(P_t^m)$. Thus,

$$\mathbb{E}[|Y_+ - \mathbb{E}[Y_+]|^3] \leq \mathbb{E}[|Y_+|^3] + \mathcal{O}(P_t^2).$$

We proceed to bound $\mathbb{E}[|Y_+|^3]$. For t small enough that Lemma 3.7 extends to $\hat{t} = 2t/5$ (via Lemma 3.5), we have

$$\begin{aligned} \mathbb{E}[|Y_+|^3] &\leq \mathbb{E}\left[2^{3(d+\varepsilon)/2}K_t^3 + 3 \cdot 2^{d+\varepsilon}K_t^2K_{2t} + 3 \cdot 2^{(d+\varepsilon)/2}K_tK_{2t}^2 + K_{2t}^3\right] \\ &= \mathbb{E}\left[2^{3(d+\varepsilon)/2}K_{t/3} + 3 \cdot 2^{d+\varepsilon}K_{2t/5} + 3 \cdot 2^{(d+\varepsilon)/2}K_{t/2} + K_{2t/3}\right] \\ &\leq (1+\eta)P_t \left(2^{d+3\varepsilon/2}3^{-d/2} + 3 \cdot 2^{\varepsilon+d/2}5^{-d/2} + 3 \cdot 2^{\varepsilon/2} + 3^{-d/2}\right) \\ &= (1+\eta)P_t 2^{d/2}2^{3\varepsilon/2} \left[\left(\frac{2}{3}\right)^{d/2} + 3 \cdot 2^{-\varepsilon/2}5^{-d/2} + 3 \cdot 2^{-\varepsilon-d/2} + 2^{-3\varepsilon/2-d/2}3^{-d/2} \right] \\ &= (1+\eta)\Delta_+ 2^{d/2}2^{3\varepsilon/2}P_t = C_\rho P_t, \end{aligned}$$

where $C_\rho = (1+\eta)\Delta_+ 2^{d/2}2^{3\varepsilon/2}$.

The bounds for Y_- follow by replacing $\varepsilon \rightarrow -\varepsilon$ throughout.

A.5. Proof of Corollary 3.14. We prove the result for $Y_{+,i} = 2^{(d+\varepsilon)/2}K_t(x, X_i) - K_{2t}(x, X_i)$; the proof for $Y_{-,i} = 2^{(d-\varepsilon)/2}K_t(x, X_i) - K_{2t}(x, X_i)$ is identical with $+\varepsilon/2$ replaced by $-\varepsilon/2$ throughout.

If we apply the Berry-Esseen to the normalized sum $\frac{\sum_{i=1}^n (Y_{i,+} - \mathbb{E}[Y_{i,+}])}{\sqrt{n \text{Var}(Y_{i,+})}}$, by Berry-Esseen, the approximation error is bounded by $C \frac{\rho_+}{\sigma_+^3 \sqrt{n}}$, where $\sigma_+^2 = \text{Var}(Y_{+,i})$, $\rho_+ = \mathbb{E}[|Y_{+,i} - \mathbb{E}[Y_{+,i}]|^3]$, and $C \leq 0.4748$.

From Lemma 3.12, we have

$$\begin{aligned}\sigma_+^2 &= \text{Var}(Y_+) \geq 2^\varepsilon \Gamma_+(1 - \eta_+^*) P_t + \mathcal{O}(P_t^2) =: C_\sigma P_t + \mathcal{O}(P_t^2), \\ \rho_+ &\leq (1 + \eta) \Delta_+ 2^{d/2} 2^{3\varepsilon/2} P_t + \mathcal{O}(P_t^2) =: C_\rho P_t + \mathcal{O}(P_t^2),\end{aligned}$$

where $C_\sigma = 2^\varepsilon \Gamma_+(1 - \eta_+^*)$ and $C_\rho = (1 + \eta) \Delta_+ 2^{d/2} 2^{3\varepsilon/2}$.

Using Taylor expansion, we see that

$$\begin{aligned}\frac{\rho}{\sigma^3 \sqrt{n}} &\leq \frac{C_\rho P_t + \mathcal{O}(P_t^2)}{\sqrt{n}(C_\sigma P_t + \mathcal{O}(P_t^2))^{3/2}} = \frac{C_\rho P_t (1 + \mathcal{O}(P_t))}{\sqrt{n}(C_\sigma P_t)^{3/2} (1 + \mathcal{O}(P_t))^{3/2}} \\ &= \frac{C_\rho}{C_\sigma^{3/2} \sqrt{P_t n}} \cdot \frac{1 + \mathcal{O}(P_t)}{(1 + \mathcal{O}(P_t))^{3/2}} = \frac{C_\rho}{C_\sigma^{3/2} \sqrt{P_t n}} (1 + \mathcal{O}(P_t)) \\ &= \frac{C_\rho}{C_\sigma^{3/2} \sqrt{n}} \left(\frac{1}{\sqrt{P_t}} + \mathcal{O}(\sqrt{P_t}) \right).\end{aligned}$$

The expansion was made on $(1 + \mathcal{O}(P_t))(1 + \mathcal{O}(P_t))^{-3/2}$ in the second line above.

Further,

$$\frac{C_\rho}{C_\sigma^{3/2}} = \frac{(1 + \eta) \Delta_+ 2^{d/2} 2^{3\varepsilon/2}}{(2^\varepsilon \Gamma_+(1 - \eta_+^*))^{3/2}} = \frac{(1 + \eta) \Delta_+ 2^{d/2}}{(1 - \eta_+^*)^{3/2} \Gamma_+^{3/2}}$$

Therefore, the normal approximation error for $\frac{1}{n} \sum_{i=1}^n Y_{i,+}$ is

$$\frac{C(1 + \eta) \Delta_+ 2^{d/2}}{\sqrt{n} \sqrt{P_t} (1 - \eta_+^*)^{3/2} \Gamma_+^{3/2}} + \mathcal{O}\left(\sqrt{\frac{P_t}{n}}\right)$$

where $C \leq 0.4748$. The proof for Y_- is identical.

APPENDIX B. BANDWIDTH

Recall $G(t) := \log S(x, e^t)$.

Algorithm 1 Bandwidth Selection via Curvature Analysis

Require: Samples $x_1, \dots, x_n \in \mathbb{R}^N$, reference point $x_0 \in \mathbb{R}^N$

Ensure: Optimal bandwidth t^* , dimension estimate \hat{d}

- 1: Choose a log-spaced grid of bandwidths $\{t_j\} \subset [t_{\min}, t_{\max}]$
 - 2: Compute $S_j = S(x_0, t_j) = \frac{1}{n} \sum_{i=1}^n K_{t_j}(x_0, x_i)$ for all j
 - 3: For each t_j , compute G'_j and G''_j using Proposition B.1
 - 4: Define $\rho_j = G''_j / (|G''_j| + \delta)$ with $\delta = 10^{-3}$
 - 5: $t^* \leftarrow \arg \max_j \rho_j$
 - 6: $\hat{d} \leftarrow 2 \log_2(S(x_0, 2t^*) / S(x_0, t^*))$
 - 7: **return** t^*, \hat{d}
-

Proposition B.1. *If we define*

$$\langle f \rangle = \frac{\sum_{i=1}^n f(u_i) e^{-u_i}}{\sum_{i=1}^n e^{-u_i}}, \quad u_i = \frac{\|x - X_i\|^2}{e^t},$$

then:

$$\begin{aligned} G'(t) &= \langle u_i \rangle, \\ G''(t) &= \langle u_i^2 - u_i \rangle - \langle u_i \rangle^2, \\ G'''(t) &= \langle u_i^3 - 3u_i^2 + u_i \rangle - 3\langle u_i \rangle \langle u_i^2 - u_i \rangle + 2\langle u_i \rangle^3. \end{aligned}$$

Proof. Set $u_i(t) = \|x - X_i\|^2/e^t$ and $K_i(t) = e^{-u_i(t)}$. Write $S = S(x, e^t) = \frac{1}{n} \sum_{i=1}^n K_i$ and define the weighted average $\langle f \rangle = \frac{1}{nS} \sum_{i=1}^n f(u_i)K_i$.

Direct calculation gives:

$$\begin{aligned} u_i' &= -u_i, \\ K_i' &= u_i K_i, \\ K_i'' &= u_i(u_i - 1)K_i, \\ K_i''' &= (u_i^3 - 3u_i^2 + u_i)K_i. \end{aligned}$$

Therefore:

$$\begin{aligned} G'(t) &= \frac{S'}{S} = \langle u_i \rangle, \\ G''(t) &= \frac{S''}{S} - \left(\frac{S'}{S}\right)^2 = \langle u_i^2 - u_i \rangle - \langle u_i \rangle^2, \\ G'''(t) &= \frac{S'''}{S} - 3\frac{S'S''}{S^2} + 2\left(\frac{S'}{S}\right)^3 \\ &= \langle u_i^3 - 3u_i^2 + u_i \rangle - 3\langle u_i \rangle \langle u_i^2 - u_i \rangle + 2\langle u_i \rangle^3. \end{aligned}$$
