Abstract While Transformer-based and standard Graph Neural Networks (GNNs) have proven to be the best performers in classifying different types of jets, they require substantial computational power. We explore the scope of using a lightweight and scalable version of *EfficientNet* architecture, along with global features of the jet. The end product is computationally inexpensive but is capable of competitive performance. We showcase the efficacy of our network in tagging top-quark jets in a sea of other light quark and gluon jets.

1 Introduction

As we enter the high-energy (HE) and high luminosity (HL) phase of the Large Hadron Collider (LHC), the study of jet physics has become more relevant than ever. ‘Fat jet tagging’ is a critical task for identifying the hadronic decays of massive particles, such as the Higgs boson, top quark, or a W or Z -boson that are produced with high momentum or ‘boost’ in a particular direction. As a result of this boost, the decay products of these standard model (SM) particles are highly collimated and can be contained within a single large-radius jet, which we call a ‘fat jet’. Scenarios like this can easily occur in various beyond the standard model (BSM) frameworks with vector-like quarks [1, 2], leptoquarks [3–5], heavy right-handed neutrinos [6, 7], supersymmetric particles with R -parity violating couplings [8, 9], to name a few. Among the above-mentioned SM particles, top quark holds a unique status. It happens to be the heaviest fundamental particle we know thus far, and unlike other quarks, it decays before hadronization. The heavy mass of the top

quark means its coupling strength with the Higgs boson is the strongest. Hence, precise measurements of top quark properties provide a consistency check of the SM. Even subtle deviations from the SM predictions for top quark interactions could hint at new physics. Moreover, the top quark mass plays a crucial role in determining the stability of the electroweak vacuum. Though the current measurements suggest that our vacuum is ‘metastable’ [10–12], this conclusion is highly sensitive to the precise values of the top quark measurements [13–15]. Identifying top quark jets as fat jets in a sea of other light quark and gluon jets, therefore, is a rather important task.

Machine learning (ML) has revolutionized this field [16–18] by moving beyond traditional methods that relied on high-level, physics-inspired features like jet mass, jet radius, n -subjettiness, energy correlation functions, etc [19–31]. Deep learning models, on the other hand, instead of using simple, hand-crafted features, train themselves to represent the jets as points in a vector space of features best suited for the subsequent classification. The inputs to these models include the four-momentum components of each constituent particle, global features that carry the kinematical properties of the jet, and particle tracking IDs whenever available. From the ML perspective, the jet physics task at hand can be divided into two broad categories: classification and generation. Both of these ‘downstream’ tasks depend on representing the raw, low-level particle or detector data associated with a jet as points in a dense, continuous vector space (feature space), ready to be effectively processed by any ML algorithm. This process, known as ‘embedding/encoding,’ allows the model to learn a more comprehensive and nuanced representation of the substructure of a jet, which can be utilized in subsequent downstream tasks.

Different types of neural networks have been developed over the last couple of decades, each tailor-made to embed input tensors of a specific type. While a Convolutional neu-

ral network (CNN) uses 2D convolutions on an image to do this, a recurrent neural network (RNN) is best suited for data presented as sequences, e.g., audio files, time series, and natural language; a graph neural network (GNN) works best on data with distinct global, node/vertex, and edge features, and so on. These models vary widely in their architectures, with completely different workflows. As one type of data can be represented in multiple ways, these models can be applied independently to them with varying performance measures. For example, pixels of a colored digital image can be represented as vectors, multi-channel 2D tensors, graphs, or even fixed-length point clouds. Historically, the calorimeter energy deposits of the constituent particles in a jet were first represented as a 2D image/grid, with pixel intensity representing their respective energy/ p_T , making CNNs—followed by a dense/linear network (colloquially known as multi-layer perceptrons or MLPs)—the default networks for jet-embedding and subsequent classification [32–39].

A more direct and fundamental approach to embedding is to represent the jet as a point cloud of its constituent particles. Each ‘point’ is a particle with its own set of features, e.g., four momentum components, particle IDs, charges, and tracking information. GNNs [40–42] are particularly well-suited for this representation. The jet is now treated as a graph where each particle is a ‘node’, and the connections between them are ‘edges’ [43–49]. Constituent information can also be represented as a varying length sequence, especially if it is ordered based on a certain property, e.g., by their transverse momentum p_T . RNNs—originally developed for processing text or speech—can then be used. The advent of the self- and cross-attention mechanisms gave us the famously parallelizable and scalable *Transformer* architecture [50]. Originally used to process and generate natural language sequences, these models can be thought of as special variations of GNNs [51], and can process jets either as sequences of constituents or unordered point clouds.

One jarring issue that plagues the existing networks with the highest accuracy in identifying various jets is the computational cost. Achieving high accuracy boils down to extracting maximal information from the jet representation. It can either be gleaned by formidably large networks or can be preprocessed and fed to a smaller network later. The former is the path taken by transformer-based models [52–54] and more costly foundational models like *Omnilearn(ed)* [18, 55, 56]. Even these, when striving for higher accuracies, bring separately extracted features to the networks ‘attention’¹. In the latter approach, when jets are considered as particle clouds or graphs, creating a fully connected graph is prohibitively costly in terms of time and computation,

¹Not adding pairwise information to the multi-head attention of the (*Par-T*) network results in a 1.2% drop in accuracy and a 20 – 30% drop in background rejection [44, 52].

mainly because the pairwise interactions (edge information²) are numerous for a jet with a large number of constituents. These challenges are either bypassed by keeping only the nearest neighbor interactions (*ParticleNet* [44]), or by representing data in a geometric algebra over space-time, equivariant under physics-motivated (Lorentz) transformations [46–48]. The newer architectures combine both of these approaches [57, 58]. Even running these state-of-the-art models on single-GPU machines becomes an ordeal, let alone training them from scratch. With the rising awareness of the virtues of Transfer Learning, more models are now pre-trained on larger datasets with multiple classes, which automatically requires significant model complexity. This considerably increases their performance, but the downside is that the cost of re-training increases many times over for specific downstream tasks.

Our objective in this work is to revisit computationally low-cost CNNs, as they implicitly utilize local, pairwise information (albeit spatially, through images) to some extent. Depending on the knowledge that the inclusion of global jet features enhances tagging efficiency [17], we explore the possibility of constructing a lightweight yet efficient network by incorporating global features with the images. Although computationally lightweight, smaller CNNs such as LeNet [59] cannot achieve competitive accuracies. Extracting more information here is equivalent to increasing image resolution and/or model complexity (depth/width). Although CNNs become notoriously computationally costly when scaled up (e.g., ResNet [60]), recent developments, such as compound scaling [61, 62], combined with depthwise and pointwise convolutions [63–67], resulted in networks that reach higher accuracies at a fraction of the cost. As all versions of *EfficientNet* were originally designed for images with higher resolution, we have built lightweight versions of those, while following the same scaling rules. We aim to explore their capabilities with and without the externally provided global features, while using LeNet as a benchmark for comparison throughout.

The paper is organized as follows. In Section 2 we provide a detailed account of our methodology. This includes machine configuration, training data preparation, model architectures, and training procedure. In Section 3 we present our results. Finally, in Section 4, we summarize our work and draw conclusions.

2 Methodology

2.1 Machine Configuration

All training and measurements, except for the measurement of inference speed, are performed on a single desktop PC

²i.e., the abstract message-passing, not physical QCD interactions.

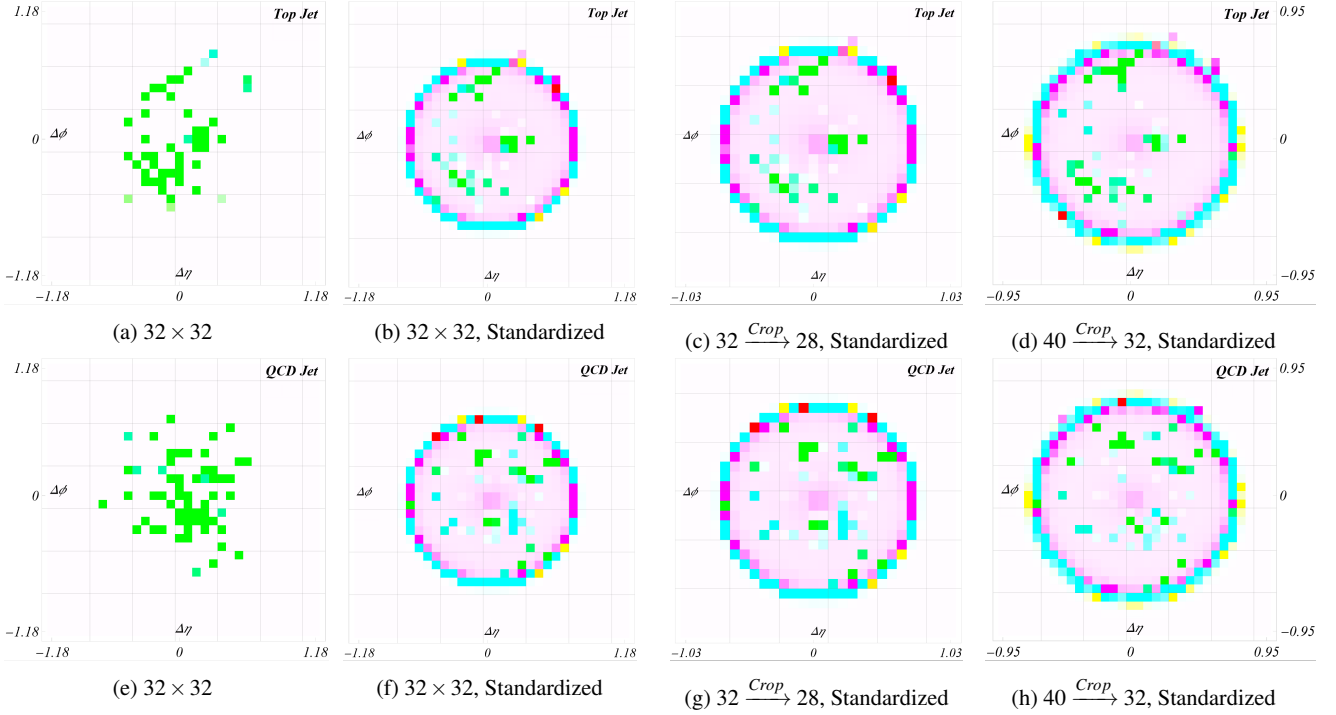

Fig. 1: Representative images of two jets for different resolutions and pixel standardization. Although images in our dataset are rendered in RGB, we present them here using the CEI 1931 XYZ color scheme [68], for better visual understanding. All images from the top panel are of one representative top jet, and those below are of one QCD jet. The first column shows the jet constituents as a 32×32 image in the $\Delta\eta - \Delta\phi$ plane, as the channels are combined and rendered. The second panel in the same row contains the same image, with the pixels standardized (the mean image of the dataset is subtracted from the original and then divided by the standard deviation image). The third column displays the images in the second, but cropped to 28×28 . The fourth column contains the same jets, first rendered in 40×40 , then cropped to 32×32 .

with 64GB RAM, a 13th generation Intel[®] i9 processor, and a 12GB NVIDIA[®] RTX A2000 graphics processor. The entire analysis is conducted in Mathematica[®] with the Wolfram Language, which uses the Apache MXNet[®] framework in the backend. The original EfficientNet architectures (before modification) were taken from the Wolfram Net Repository [69]. To compare the inference speed of CNNs in this work with some external models, inference times were calculated on another machine with an 11GB NVIDIA[®] GeForce GTX 1080-Ti graphics processor.

2.2 Data: Images from Constituents

We have used a pre-existing dataset³ that contains both top-quark and mixed light-quark-gluon jets. The objective, as mentioned before, is to identify top quark jets as signals and tag them as fat jets amid the sea of other jets. The events were generated with 14 TeV center-of-mass energy using Pythia8 [70] followed by detector simulation performed using Delphes [71]. The jets were constructed using the anti- k_T algorithm [72] with FastJet [73]. The pseudorapidity $|\eta_j|$

is required to be < 2 for the fat top quark jet, whereas the radius parameter is chosen to be 0.8. It is ensured that a matched parton-level top exists within $\Delta R = 0.8$ of this signal jet. Moreover, all decay products of the top quark are required to be within $\Delta R = 0.8$ of the jet axis. 4-momenta information is stored for the leading 200 jet constituents. The leading top-quark jets lie within a p_T range of 550 – 650 GeV. The total sample consists of one million top jets alongside another million non-top jets, which are treated here as background. The dataset is divided into training / validation / test (1.2M/0.4M/0.4M) sets.

We pre-process the data to create 3-channel images with transverse momentum (p_T), mass (m), and energy (E) in each channel, respectively. To create each channel from the jet constituents, the hardest constituent is considered to be the center of the channel, and the rest of the image is constructed by binning the remaining constituents in two dimensions: the difference in pseudo-rapidity ($\Delta\eta$) and that in the azimuthal angle ($\Delta\phi$). The paper associated with the original dataset [36] assumes the calorimeter resolution to be $0.04 \times 2.25^\circ$, where a fat jet with a radius parameter $R = 0.8$ can be covered with 40×40 pixels. Fixing the bin sizes thus keeps our jet images at this dimension or less (32×32). Due to these choices and the nature of the dataset,

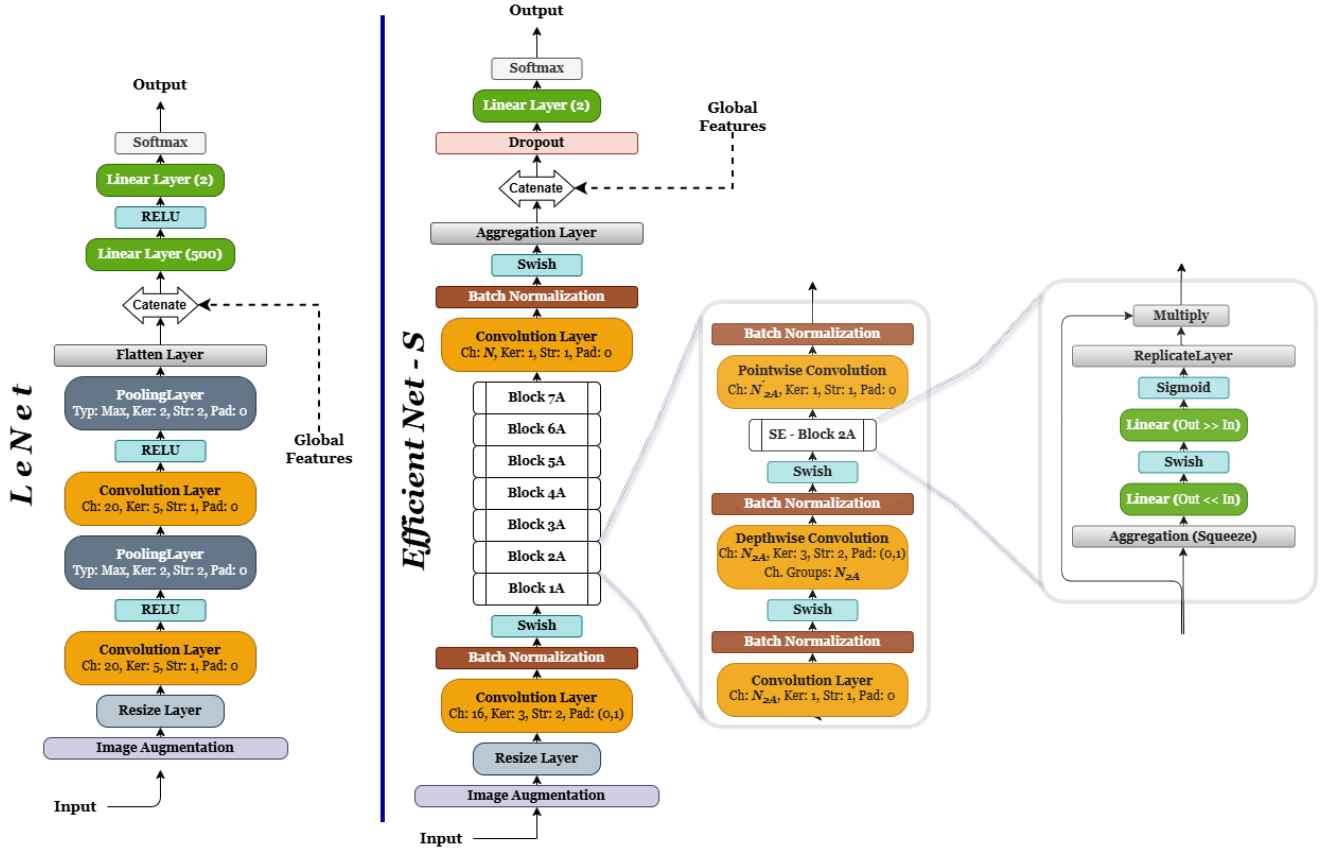

Fig. 2: Schematics of network architectures used in this work. On the left is *LeNet*, used as the benchmark CNN model. On the Right is the simplest Efficient Net (small) used. Representative schematics of the *M-Conv* blocks and the squeeze and expand residual blocks within those are also shown.

both $\Delta\eta$ and $\Delta\phi$ axes are retained from -1.2 to 1.2 , without the loss of any constituents (see Figs (1a) and (1e)). Unlike the original paper, we do not fix the axis of the second hardest object; rather, we use an image augmentation layer to randomly flip the image along either axis or both during training. We do not use random cropping, as the jets are constructed objects and can always be centered around the hardest p_T constituent for all practical applications. Furthermore, to use *N-subjettiness* later in our analysis, we also require each jet to have at least 4 constituents, which drops a meager 33 jets from the 201.8K dataset.

Standardization of input data has become common in ML, as it has been found to improve the performance of generic neural networks. We perform this standardization by creating a ‘mean’ and a ‘standard deviation’ image using a large number of random samples from the dataset. We respectively subtract from and divide every sample by the values of these arrays. This clearly isolates a fairly circular region in the $\Delta\eta - \Delta\phi$ plane containing the bulk of the jet structure (see Figs (1b) and (1f)). During some preliminary runs, it has been consistently observed that using images where the central region covers most of the image field

yields better classification performance. Thus, we apply a center-crop to the 32×32 images, making them 28×28 (see Figs (1c) and (1g)). A similar size of the central region is obtained for the 40×40 images when they are cropped to 32×32 (see Figs (1d) and (1h)). We keep more of the field of images than is usual practice in the community, where final images are generally cropped to $R = 0.8$ [34–36]. Our crops vary within $0.96 \leq R \leq 1.05$.

2.3 Data: Jet-Level Information

We have combined some global features of the jet to ascertain how much they improve the tagging efficiency of the CNNs. The features used in this work are inspired by refs [17, 74]. The original dataset provides the four-momentum of up to 200 constituents per jet, from which all global features can be computed. For this purpose, we employ the *fastjet* package along with *EnergyCorrelator* contrib from *fastjet-contrib-1.3.2*.

In addition to the global four-momentum of the jet, our feature set includes the *N-subjettiness* variables [19], as well as several series of observables constructed from Energy

Correlation Functions [22] and generalized correlator functions [23]. The complete list of variables is as follows:

- Jet four-momentum: $p_T, \eta, \phi, m_{\text{jet}}$
- Number of constituents: N_{cons}
- N -subjettiness ratios: $\tau_{21}^\beta, \tau_{32}^\beta, \tau_{43}^\beta, \tau_{54}^\beta, \tau_{65}^\beta$ for $\beta = 0.5, 1.0, 2.0$
- C -series: $C_1^\beta, C_2^\beta, C_3^\beta$ for $\beta = 1.0, 2.0$
- D -series⁴: $D_2^{\alpha,\beta}$ for $\alpha, \beta = 1.0, 2.0$, and the four D_3 variables defined in [17]
- U -series: $U_1^\beta, U_2^\beta, U_3^\beta$ for $\beta = 0.5, 1.0, 2.0$
- M -series: M_2^β, M_3^β for $\beta = 1.0, 2.0$
- N -series: N_2^β, N_3^β for $\beta = 1.0, 2.0$
- L -series: L_2, L_3 as defined in [74]

Certain global features, such as U_3^β and M_3^β , require at least 4 constituents for their computation. As mentioned in the previous sub-section, we discard all jets with $N_{\text{constituents}} < 4$. For complete definitions and a detailed description of these variables, we refer the reader to ref.s [17, 74]

2.4 Model Architecture

Historically, one of the most successful convolutional neural networks (CNNs), LeNet [59], is also the oldest and one of the simplest. LeNet-5, with alternating convolutional and pooling layers, has been the dependable standard for smaller images (see the left side of Fig. (2) for its architecture). Over the decades following LeNet, CNNs continued to scale up to classify images at increasingly higher resolutions. AlexNet [78], Inception nets [79, 80], ResNets [60] and their wider versions [81], DenseNets [82], and MobileNets [63–66] are only a few examples of these. To go deeper and wider, these newer architectures used varied techniques, such as ‘residual’ connections to feed information from earlier layers to the latter parts of the network, point-wise (1×1) and depth-wise convolutions for dimension reduction to remove computational bottlenecks, batch normalization, and mixtures of these methods [83, 84]. Targeting general-purpose image classification, these models were optimized for the ImageNet dataset [85, 86] and its equivalents; thus, computationally, they are quite expensive.

Though scaling CNNs according to image resolution has been attempted before [87], EfficientNets [61, 62] were the first to solve the scaling problem by using ‘compound scaling’, connecting network *depth* and *width* to image *resolution*. Given a baseline network (found from a neural architecture search, or NAS), these quantities scale as:

$$\begin{aligned} \text{depth coefficient } d &= \alpha^\phi \\ \text{width coefficient } w &= \beta^\phi \\ \text{resolution coefficient } r &= \gamma^\phi, \end{aligned} \quad (1)$$

⁴The parameter choices for the D -series features follow [75–77].

| Layers | Input Resolution | |
|-------------------|--------------------------|--------------------------|
| | $3 \times 40 \times 40$ | $3 \times 64 \times 64$ |
| Conv 3×3 | $16 \times 20 \times 20$ | $16 \times 32 \times 32$ |
| Block 1A | $8 \times 20 \times 20$ | $8 \times 32 \times 32$ |
| Block 2A | $8 \times 10 \times 10$ | $16 \times 16 \times 16$ |
| Block 3A | $16 \times 5 \times 5$ | $16 \times 8 \times 8$ |
| Block 4A | $24 \times 3 \times 3$ | $32 \times 4 \times 4$ |
| Block 5A | $32 \times 3 \times 3$ | $48 \times 4 \times 4$ |
| Block 6A | $56 \times 2 \times 2$ | $80 \times 2 \times 2$ |
| Block 7A | $96 \times 2 \times 2$ | $136 \times 2 \times 2$ |
| Conv 3×3 | $400 \times 2 \times 2$ | $536 \times 2 \times 2$ |
| Aggregate | 400 | 536 |
| FC & Out | 2 | 2 |

Table 1: *Effnet-S* configurations for two different input resolutions. For more details, see sec. 2.4.

where $\alpha \geq 1, \beta \geq 1, \gamma \geq 1$. Here, increasing ϕ , the scaling parameter, increases the complexity of the network in a compounded manner. Noting that doubling the net-depth doubles the computational cost (floating point operations per second, or FLOPS), but doubling the other two quadruples the FLOPS, these also follow an empirical constraint: $\alpha \cdot \beta^2 \cdot \gamma^2 \simeq 2$, so that increasing ϕ by some ϕ_0 increases the FLOPS by 2^{ϕ_0} . The authors of the first EfficientNet paper performed a grid search on α, β , and γ and obtained the values 1.2, 1.1, and 1.15, respectively. Starting with $\phi = 0$ and increasing ϕ by 1 each time, they obtained eight networks (B_0 to B_7) with increasing complexity. The base network (B_0) works on arrays of dimension 224×224 , while the largest of these models (B_7) takes in arrays of dimension 600×600 . There are seven main building blocks of an EfficientNet, each containing multiple parts. Building upon other successful lightweight models [64, 67], EfficientNets replace a fully convolutional operation with a depthwise convolution (a single filter per channel) and a pointwise (1×1) convolution (see the blown up schematic of *Block 2A* in Fig. (2)). This significantly reduces the computational cost while maintaining similar performance. When stacked together, the blocks mentioned above also perform a function known as inverted bottlenecking, embedding the input manifold into a lower dimensional manifold. Each of these blocks also contains a *squeeze and expansion* block [88], with a residual connection maintaining the information flow, as well as a combination of *Swish*, *RELU*, and *Sigmoid* activation functions. More details can be found in the original paper [61]. While the width coefficient scales up the channel dimension of each block, the depth coefficient determines the number of times each type of block is repeated, making the network deeper. These networks also scale up the

Table 2: Single number performance metrics for ML models performed on the total test dataset. From the second to the seventh column, we respectively report the input array sizes, the resolution of the generated jet images ($A \rightarrow B$ means the original image was $A \times A$, and it was cropped to $B \times B$), total number of parameters in the network, inference time for 100 jets in milliseconds, overall accuracy, and area under the ROC curve (AUC). The last two columns list the QCD background rejection at top tagging efficiencies of 50% and 30% respectively.

dropout probability to regularize the larger models. All versions of EfficientNet outperform other CNNs that are much larger in size (in terms of accuracy) while being faster during inference (B_0 , with 5.3 M parameters, achieves a top-5 accuracy of 93.3% for ImageNet, compared to the widely used ResNet-50 (26 M parameters)—which has a top-5 accuracy of 93.0%; the FLOPS for ResNet-50 is 11 times that of EfficientNet- B_0).

We begin with LeNet in this analysis as a benchmark for performance. Following its historical usage, the smallest resolution of jet images we use is 28×28 , increasing to 32×32 and 40×40 . Images larger than these make the jet constituents sparser, and CNNs with even higher-resolution inputs are needed for their analysis. The network we focus on here is *EfficientNet*. While they have been used on smaller images, such as the CIFAR-10 and CIFAR-100 datasets, these

have been upsampled to fit the 224×224 input dimensions⁵. This defeats one of the main purposes of this work (working with constrained computational resources), both in terms of RAM and VRAM.

To circumvent this without changing the hyperparameters of the original EfficientNet architecture (and using the prescribed values of α , β , and γ), we use negative ϕ values to scale down the input resolution. The smallest resolution thus achieved is 36×36 . Any smaller, and the bottlenecks within the network would not hold without modification. We choose the starting resolution to be 40×40 (in accordance with the resolution of the simulated calorimeter), corresponding to $\phi \simeq -12.33$. A larger version was also

⁵ Author’s answer: <https://github.com/tensorflow/tpu/issues/421>.

Fig. 3: ROC curve (signal efficiency vs. background rejection) for some of the networks (with some metric highest among others; table (2) has them in bold-face). The solid lines are for models working on both images and global features, dashed ones correspond to those with only images as input.

created with 64×64 inputs, for $\phi \simeq -8.96^6$. The other important parameter to set is the dropout probability, which is gradually increased from B_0 to B_7 , as more regularization is needed for larger networks. We linearly extrapolated these values using the width and depth coefficients and used the corresponding values for our networks. Evidently, the much smaller size of our networks resulted in significantly less dropout regularization. Altogether, we will denote this smaller architecture as EfficientNet-Small (*EffNet-S*) for this work. For these values of ϕ , every block appears only once in the smaller *EffNet-S* structures. We have thus indexed the blocks ‘ i -A’ ($i = 1, 2, \dots$), to keep the possibility of larger networks open⁷. Table (1) lists the input dimensions for this architecture for two different input resolutions: 40×40 and 64×64 .

⁶Similar efforts can be found here: <https://github.com/qubvel/efficientnet/issues/26>

⁷This raises an obvious question: as these CNNs were fine-tuned to detect specific *shapes* (with detail) from larger images, unlike in our case—where the jet-images are smaller and are mere representations with a much larger importance to finer structures—could it be possible to systematically search for and create versions of scalable networks for this specific task, albeit smaller? Though intriguing, this question is outside the scope of the present work. However, glimpses of this possibility may be perceived from the present analysis.

2.5 Training

Although we load the validation and test datasets into RAM as a whole, due to our choice of confining ourselves to a single mid-range PC with 64GB RAM, we use a type of data piping for the training dataset. We load 300,000 training data at a time, which we will call a ‘*round*’ from now on. Each round is trained until the validation loss stops decreasing for 10 epochs. An image of the trained network is saved from each round and used in the next one. This is done for 15 (18) rounds for 32×32 (40×40) image representation of jets to ensure that the entire dataset is adequately represented. For most of the models used in this work, we repeat the process, starting with the last trained network, and use the same rounds again. This way, the rounds mimic the behavior of epochs, while storing the datasets beforehand reduces computation time. We then evaluate the accuracy of each of these models on the test dataset, and the one with the highest accuracy is chosen as the best version of that specific model architecture. All further measurements are performed on this iteration of the model.

To ensure optimal computation time, we choose batch sizes depending on whether the memory dedicated to the graphics card can handle them without overflowing into the SWAP memory. For *EffNet-S* (64) a batch size of 2048 is used. For all other networks, it is fixed at 4096. We use the ADAM optimizer [89] with default settings ($\beta_1 = 0.9$, $\beta_2 = 0.99$, and $\epsilon = 10^{-5}$, along with the default learning rate update schedule) to minimize the cross-entropy loss, where we wait for a fixed number of *epochs* (generally 10) for the last minimum loss to be updated; otherwise, we stop the training.

The global features of the jets are standardized and utilized in the second part of the analysis, in conjunction with the images. These are concatenated with the output of the ‘*Flatten Layer*’ of *LeNet* and, in the case of *EffNet-S*, that of the ‘*Aggregation Layer*’, as can be seen from Fig. (2). Pre-trained networks are faster to retrain and reach higher accuracies after modification—a fact that has been re-established in recent attempts at foundational models in jet applications. Keeping that in mind, we use the first part of the best network of a particular architecture and add an MLP block to it in this part of the analysis.

We retrain the best network of each architecture nine additional times, with a representative subset of the dataset, to obtain the uncertainties arising from random weight initialization.

3 Results

Table (2) lists all single-number performance metrics for the networks explored in this analysis. The table is divided into three blocks: the first block contains all the information

about the *LeNet* architecture, the second one about *EffNet-S*, and the third one lists some of the publicly available information about CNNs used previously as top-taggers for comparison. We have obtained results for *LeNet*-type networks with three different input resolutions: 28×28 , 32×32 , and 40×40 . Versions of *EffNet-S* are of two types: 40×40 and 64×64 . Images are generated in two ways: 32×32 images cropped to 28×28 and 40×40 images cropped to 32×32 , as explained in sec. 2.2. Each network is run on all images with cropped resolution (col. 3 of tab. 2) less than or equal to its input dimension (col. 2 of tab. 2). Networks with a specific architecture and input resolution optimized for maximum accuracy are used to create versions that can also process the global features.

LeNets with increasing input array-sizes, when applied only to images cropped to 28×28 , gain marginally in performance across all metrics. Incorporating global features clearly increases the discriminative power—especially background rejection—of the networks, and the effect is more prominent for higher image resolutions. This is expected, as *LeNet* is a conventional CNN. Full convolutions with a large kernel size (5) extract more information from the images, albeit at a higher computational cost and a heavier network. The *LeNet-40* is 2.9(2.7) times the size of *LeNet-40* without (with) global features.

The smallest *EffNet-S*, while applied only to images, outperforms all *LeNets*, while being 1/8-th the size of the largest *LeNet* and in terms of the total number of parameters. Its performance is best when the input images are $32 \xrightarrow{\text{Crop}} 28$, and it drops a little for the larger images. The possible reason is that the ‘MB-Conv’ blocks with bottlenecks in *EffNet-S* do not perform at the level of full convolutions when analyzing sparse pixel-level information, and networks with larger input arrays are needed for proper classification. Adding global features is beneficial here as well, but the effect is less prominent for larger networks. One possibility is that the extra MLP block after the last Aggregation layer contributes far less than the rest of the network. Analyzing higher input sizes and higher image resolutions can shed more light on this. We have shown the best metrics in each column in bold-face, for both the cases with and without global features.

Fig. (3) shows the signal (top) efficiency vs. the background (QCD) rejection curves for those representative models for which at least one of the metrics is highest among others (those in bold-face in table 2).

In the case of other CNNs, the entries for the ‘Image Resolution’ column are calculated in the following way: we know these images were created 40×40 (*DeepTop*) and 64×64 (for *ResNext*) for $R = 0.8$. This corresponds to 60×60 and 96×96 for $R = 1.2$, which is our case. These are all grayscale images with only one channel for p_T . All networks used in this analysis that utilize the global features outperform the classic *DeepTop* CNN structure in terms of

accuracy, if not in background rejection. *ResNeXt-50* has a much better performance, but it is considerably heavier than the *EffNet-S* (the best performing global feat. variant is 1/7-th in size of *ResNeXt-50*). These nets are faster as well. The longest inference time for *EffNet-S* is half of that for *ResNeXt-50*.

4 Conclusion

Jet tagging, a classification problem that aims to identify jets originating from different particles (top quarks, Higgs boson, gauge bosons, light quarks, or gluons), remains a challenging, albeit one of the most important tasks, especially in the context of a hadron collider like the LHC. Machine learning has now replaced traditional use of hand-crafted features to become an integral part of jet physics studies. Depending on the network used, jets are treated as images, sequences, trees or graphs. Existing literature shows that transformer based networks, which treat jets as particle clouds or graphs, perform the best. To achieve the highest possible accuracy, incorporating pairwise information is crucial. However, given the large number of pairwise interactions among the constituents of a jet, creating a fully connected graph becomes a computationally costly affair. CNNs, on the other hand, while being computationally low-cost, treat jets as images/arrays denoting the spatial arrangement of constituent particles in terms of energy, momentum, and mass; thus can utilize at least some local pairwise information. One can additionally incorporate global features of the jets to either directly to the images or to the network to enhance the jet identification accuracy. We have explored the possibility of combining these features and construct a computationally lightweight but efficient CNN-based network that can compete with other similar architectures.

With traditional CNNs, larger/deeper networks are needed to extract maximal information from the jet images, as opposed to typically lightweight CNNs like *LeNet*. Scaled up CNNs, such as *ResNets* are computationally costly. Using recent advancements in the construction of CNNs, we have used lightweight versions of *EfficientNet* to circumvent this issue. Although these were built to work on higher resolution images, one can follow a set of prescribed scaling rules to construct a network applicable for low resolution jet images as well. We have performed a comparative study with and without externally provided global features. Results for *LeNet* are also provided for comparison.

We observe that adding global features to the models, along with the images, results in better accuracy. Although this increase is somewhat monotonic with increasing image resolution for fully convolutional models, such as *LeNet*, the corresponding relationship for *EffNet-S* is not so straightforward. Increasing the input array size also improves the overall performance.

This exploration leads to three observations: first, there needs to be a systematic architecture search for versions of scalable models such as EfficientNet, tuned for jet classification; second, adding global jet features, in addition to the constituent information, makes it easier for smaller models to perform better; last, but not the least, as jets can be represented in multiple types of data, one can combine the strengths of different network architectures and build a hybrid ensemble of lightweight networks capable of achieving high accuracy while working with various representations of the same jet, e.g., image, constituent four-momenta, and global jet features. This ‘mixture of experts’ approach has the potential for superior performance, leading to better signal-to-background discrimination. Exploring this idea is beyond the scope of this paper, but it is something that we plan to work on as a subsequent project.
