ABSTRACT

Low-grade gliomas frequently present *IDH1* mutations that define clinically distinct subgroups with specific prognostic and therapeutic implications. This work introduces a Multimodal Oncology Agent (MOA) integrating a histology tool based on the TITAN foundation model for *IDH1* mutation prediction in low-grade glioma, combined with reasoning over structured clinical and genomic inputs through PubMed, Google Search, and OncoKB. MOA reports were quantitatively evaluated on 488 patients from the TCGA-LGG cohort against clinical and histology baselines. MOA without the histology tool outperformed the clinical baseline, achieving an F1-score of 0.826 compared to 0.798. When fused with histology features, MOA reached the highest performance with an F1-score of 0.912, exceeding both the histology baseline at 0.894 and the fused histology-clinical baseline at 0.897. These results demonstrate that the proposed agent captures complementary mutation-relevant information enriched through external biomedical sources, enabling accurate *IDH1* mutation prediction.

Index Terms— Oncology Agent, Multimodal, *IDH1* mutation, Low-Grade Glioma, Histopathology

1. INTRODUCTION

Isocitrate dehydrogenase 1 (IDH1) mutations are highly prevalent in adult-type diffuse low-grade gliomas, occurring in approximately 50–81% of WHO grade II and III tumors [1]. These mutations identify a clinically important subgroup of gliomas characterized by slower progression, longer survival, and distinct therapeutic response profiles, making their accurate detection critical for diagnosis and prognostic assessment [1, 2].

Most deep learning models for *IDH1* mutation prediction are unimodal, relying on a single data source such as histopathology or radiomics and overlooking the broader clinical context [3]. Recent multimodal approaches integrating complementary sources of information, such as clinical, imaging, and histological data, have shown improved accuracy in *IDH1* mutation prediction [4].

Recently, agent-based architectures have been proposed to unify heterogeneous clinical data through large language model (LLM) reasoning, enabling interpretable and evidence-grounded decision-making in oncology. Such agents have been applied to early breast cancer detection using imaging and clinical data [5], and to hepatocellular carcinoma management integrating radiological and clinical information [6]. The oncology agent introduced by Ferber *et al.* [7] integrates clinical, genomic, histological, and radiological data with external knowledge sources such as PubMed and OncoKB, demonstrating autonomous multimodal reasoning across gastrointestinal cancers.

In this work, we propose a Multimodal Oncology Agent (MOA) for *IDH1* mutation prediction in Low-Grade Glioma (LGG), using 488 patient cases from the TCGA-LGG cohort. We developed a histology tool based on the TITAN foundation model for *IDH1* mutation prediction, which was integrated into the agent’s reasoning framework alongside structured clinical and genomic inputs. We quantitatively evaluated this agent by generating MOA reports excluding the histology tool and comparing their predictive embeddings against clinical and histology baselines, as well as their fusion with histology features, enabling a systematic assessment of the MOA’s multimodal reasoning performance. Our experiments demonstrate that the proposed agent effectively captures complementary, mutation-relevant information across modalities, enriched through external biomedical sources, for accurate *IDH1* mutation prediction.

2. MATERIALS AND METHODS

2.1. The Dataset

Experiments were conducted on the TCGA-LGG cohort, comprising diagnostic Whole-Slide Images (WSIs), somatic mutation profiles, and clinical records, including demographic, diagnostic, and treatment data. Only patients with confirmed *IDH1* mutation status were included, resulting in 488 cases (374 mutant and 114 wildtype). Each patient had one or more diagnostic WSIs scanned at 40× magnification; the slide with the largest tissue area was retained per patient.

Radiology data were not included in this study.

2.2. Histology Tool for *IDH1* Status Prediction

We built a histology tool for *IDH1* mutation prediction and integrated it into the agent’s toolset. Diagnostic WSIs were tiled into 512×512 patches at $20\times$ magnification, retaining regions with at least 90% tissue content. Slide-level embeddings (768-dimensional) were extracted using TITAN [8] from CONCH foundation model [9] patch features and classified with a four-layer Multi-Layer Perceptron (MLP). Within the agent framework, the tool is dynamically invoked when a valid WSI path or TITAN feature file is provided in the patient case, processing the input and returning an *IDH1* mutation probability and binary prediction.

2.3. MOA Configuration for *IDH1* Status Prediction

Inspired by the oncology agent framework developed by Ferber *et al.* [7], the proposed framework integrates multiple domain-specific tools, including PubMed and Google for literature and web evidence retrieval, and OncoKB [10] for curated knowledge on clinically actionable genomic alterations, enabling multimodal clinical reasoning. The MOA operates autonomously: given a textual patient context and query, MOA selects and invokes the relevant tools, integrates their outputs, and synthesizes them into a comprehensive report. For this study, the agent was configured for *IDH1* mutation prediction in LGG. The MedIttron corpus of clinical guidelines [11] served as the primary knowledge base, filtered with glioma-specific keywords (e.g., glioma, oligodendroglioma) to retain 187 relevant documents, which were preprocessed and embedded into a local Chroma database for retrieval. Figure 1 illustrates the configured MOA workflow for *IDH1* mutation prediction, showing how MOA orchestrates tool use to generate the final report containing the *IDH1* mutation status.

2.4. MOA Reports for Quantitative Evaluation

Unlike the original framework, which assessed agent generated reports qualitatively (e.g., for correctness or completeness), we quantitatively examined whether these reports encode measurable information related to *IDH1* mutation status that can be detected through a predictive model.

2.4.1. Report generation

Reports were generated for all 488 patients by constructing structured patient cases containing demographic details (e.g., age, sex), diagnostic information (e.g., tumor class, histologic morphology), treatment records (e.g., treatment type, therapeutic procedure). Molecular summaries were derived from The Cancer Genome Atlas (TCGA) somatic mutation profiles, filtered to retain genes frequently mutated in LGG

and annotated in OncoKB. Two genes, *TP53* and *CIC*, met these criteria, with validated oncogenic annotations available for 208 of the 488 patients. To prevent bias or label leakage, the histology tool, which outputs an *IDH1* mutation probability, was disabled during report generation. Each constructed patient case, together with a fixed query applied uniformly across all patients, was then provided as input to the MOA, which produced the final report by invoking the appropriate tools (PubMed, Google Search, and OncoKB).

2.4.2. Report Embedding and Evaluation

The 488 MOA reports were cleaned and standardized before embedding. We used the gte-base-en-v1.5 [12] sentence transformer, a general-purpose long-context model supporting sequences up to 8,192 tokens. For comparison, the same encoder was applied to the clinical text of the 488 patients, derived from diagnosis, treatment, and demographic variables, while the same variables were also one-hot encoded as an additional baseline. The resulting embeddings were used as input to a four-layer MLP trained for *IDH1* mutation status prediction, quantifying how much mutation-related information is captured in the MOA reports and in the clinical data alone. Molecular summaries were excluded from the baselines due to missing values in 280 patients.

2.5. Integrated Evaluation of the Complete Agent

To assess the full oncology agent on *IDH1* mutation prediction, the embeddings of MOA reports (excluding the histology tool) were concatenated with the corresponding slide embeddings extracted using TITAN. The fused representations were classified using the same four-layer MLP as in previous experiments. This setup, illustrated in Fig. 2, quantifies the joint contribution of the agent’s textual reasoning and histological analysis to mutation-level prediction.

3. EXPERIMENTS AND RESULTS

3.1. Implementation details

Experiments were conducted as an ablation study evaluating the MOA with and without the histology tool. All experiments used five-fold stratified cross-validation and a four-layer MLP trained with weighted cross-entropy loss. The Adam optimizer employed a learning rate of 1×10^{-4} and weight decay of 1×10^{-5} . Text and histology embeddings were Z-score normalized. Models were trained with a batch size of 32 and evaluated with accuracy, F1-score, and the Area Under the ROC Curve (AUROC).

3.2. Agent Performance and Component Analysis

All results are summarized in Table 1. The clinical text baseline, encoded with the sentence-transformer, achieved mod-

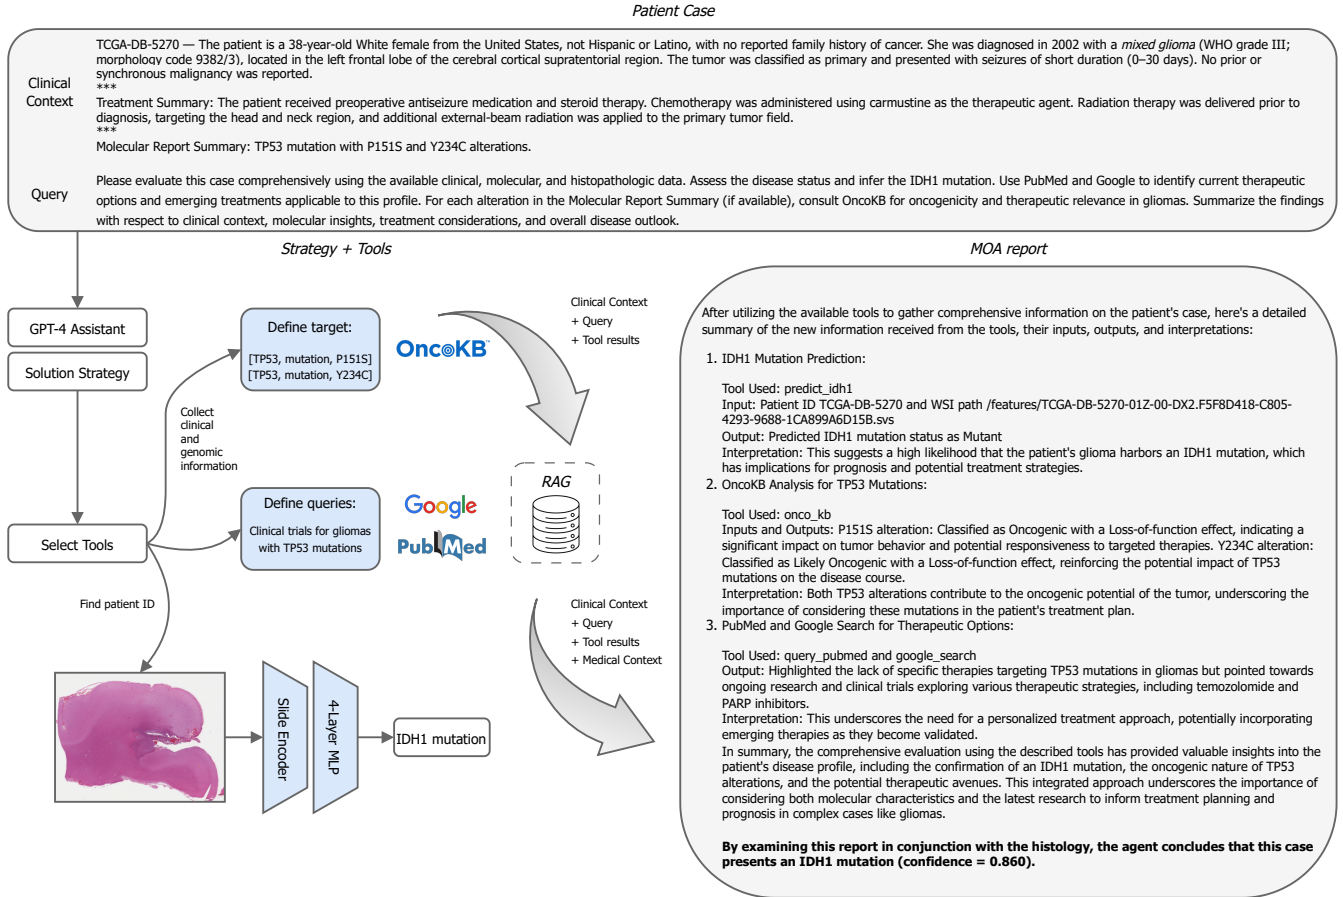

Fig. 1. Demonstration of the MOA framework on a patient case. The GPT-4 Assistant autonomously selects tools based on the clinical context and query, retrieves evidence from OncoKB, PubMed, Google, and the histology tool for *IDH1* mutation prediction, and integrates all outputs through RAG reasoning. The synthesized findings are compiled into an MOA report.

erate performance ($F1 = 0.789$), while the one-hot encoding of structured clinical variables yielded slightly higher results ($F1 = 0.798$), showing that a simpler representation was more effective in this case. In contrast, the MOA reports, encoded with the same sentence-transformer and without the use of the histology tool, achieved better overall performance (Accuracy = 0.802, $F1 = 0.826$, AUROC = 0.751) than both clinical base-lines. This demonstrates that the agent enriches clinical information through contextual reasoning over patient data and external biomedical knowledge, capturing mutation-relevant patterns beyond explicit clinical features.

The histology tool achieved the strongest standalone performance ($F1 = 0.894$), confirming the high discriminative power of TITAN embeddings for *IDH1* mutation prediction from WSIs. When concatenated with clinical variables, the performance improved only slightly ($F1 = 0.897$), indicating that the histology features already capture key information related to *IDH1* mutation. In contrast, fusing the MOA report embeddings with histology features led to the highest over-

all performance (Accuracy = 0.915, $F1 = 0.912$, AUROC = 0.892). This demonstrates that the complete agent integrates complementary information from external biomedical knowledge with histological representations, leading to improved prediction of *IDH1* mutation status.

4. CONCLUSION AND FUTURE DIRECTIONS

In this paper, we proposed a multimodal oncology agent for *IDH1* mutation prediction in LGG. Unlike prior studies that evaluated agent reasoning qualitatively, we introduced a systematic protocol to measure the predictive content of MOA-generated reports. The sentence-transformer used to encode the reports naturally handles missing information. The results show that text-based reasoning grounded in PubMed, Google Search, and OncoKB captures mutation-relevant information, while integration with a histology tool further enhances performance through complementary morphological features.

Beyond predictive performance, an important aspect of

Table 1. Performance of MOA variants with and without the histology tool, compared to clinical baselines and the standalone histology tool, for *IDH1* mutation prediction on the TCGA-LGG cohort. Values are mean \pm std over 5 folds.

Component Evaluated	Encoder	Model	Accuracy	F1	AUROC
Clinical Text	gte-base-en-v1.5	MLP	0.736 \pm 0.09	0.789 \pm 0.05	0.700 \pm 0.04
Clinical Variables	One-hot	MLP	0.756 \pm 0.06	0.798 \pm 0.02	0.730 \pm 0.03
MOA (without Histology)	gte-base-en-v1.5	MLP	0.802 \pm 0.09	0.826 \pm 0.05	0.751 \pm 0.06

the agent is its ability to handle missing data by adapting tool selection to the available inputs, demonstrating flexibility for real-world clinical application. Future directions include extending MOA with radiology and pathology reports to enrich multimodal reasoning, and exploring open-weight language models for the agent’s reasoning and tool orchestration.

5. COMPLIANCE WITH ETHICAL STANDARDS

This research study was conducted retrospectively using human subject data made available in open access by TCGA. Ethical approval was not required, as confirmed by the license associated with the open-access data.
