## ABSTRACT

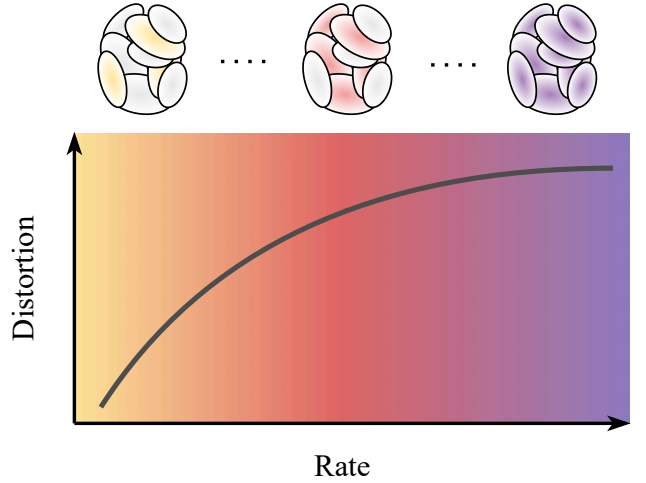

Recent advances in neural scene representations have transformed immersive multimedia, with 3D Gaussian Splatting (3DGS) enabling real-time photorealistic rendering. Despite its efficiency, 3DGS suffers from large memory requirements and costly training procedures, motivating efforts toward compression. Existing approaches, however, operate at fixed rates, limiting adaptability to varying bandwidth and device constraints. In this work, we propose a flexible compression scheme for 3DGS that supports interpolation at any rate between predefined bounds. Our method is computationally lightweight, requires no retraining for any rate, and preserves rendering quality across a broad range of operating points. Experiments demonstrate that the approach achieves efficient, high-quality compression while offering dynamic rate control, making it suitable for practical deployment in immersive applications. The code will be provided open-source upon acceptance of the work.

**Index Terms**— 3D Gaussian Splatting, compression, dynamic rate

## 1. INTRODUCTION

The demand for immersive multimedia experiences has grown rapidly, driven by applications in augmented or virtual reality and interactive entertainment, to mention a few [1]. Realistic scene representation and efficient rendering are now more central than ever to enabling such experiences, where high visual fidelity or realism must be delivered under computational and bandwidth constraints. As a result, research into novel 3D scene representations has recently accelerated, aiming to strike a balance between realism, efficiency, and scalability [2].

A pivotal advance in this area was introduced by neural radiance fields (NeRFs) [3], which demonstrated that neural implicit functions could effectively synthesize photorealistic views from sparse imagery. Despite their success, NeRFs suffer from substantial computational overhead in both training and rendering. More recently, 3D Gaussian Splatting

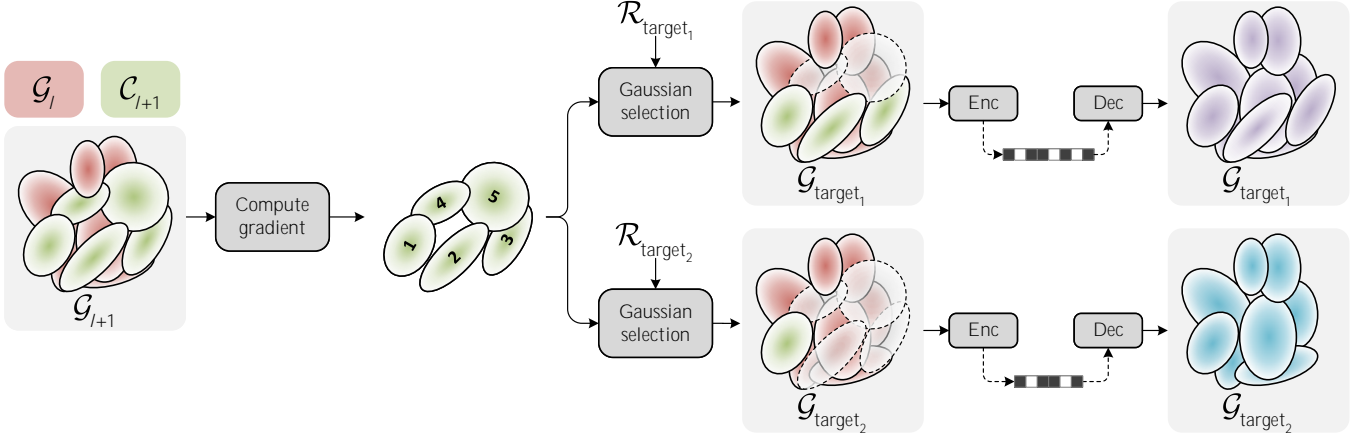

**Fig. 1:** We present **RAVE**, the first method enabling *rate-adaptive visual encoding* for 3DGS approaches. Unlike existing methods that require multiple separate training runs, RAVE produces a *continuous* rate–distortion curve in a single, efficient end-to-end training. This allows seamless adaptation of the bitrate to different constraints without retraining, offering both state-of-the-art quality and practical deployment.

(3DGS) [4] has emerged as a powerful alternative, relying on explicit point-based representations to enable real-time rendering. This shift has further boosted the field [5, 6], offering a practical pathway toward interactive immersive media with an end-to-end learning fashion.

Nevertheless, 3DGS also faces inherent challenges. While its explicit representation allows for fast rendering [7], the memory footprint for rendering can grow significantly [8]. Beyond efficiency, scaling the training process remains computationally demanding, often requiring significant optimization steps to achieve competitive quality [9]. These issues hinder widespread adoption in resource-constrained environments, where lightweight yet flexible solutions are crucial.

To overcome these limitations, several compression techniques have been proposed to reduce both storage and transmission costs. In this setting, a common approach is to

<sup>\*</sup>Co-first authorship

**Fig. 2:** Overview of our method. We compute per-anchor gradient scores once and rank Gaussians by importance. For any target rate  $\mathcal{R}^{\text{target}}$ , the top-ranked Gaussians are selected to form  $\mathcal{G}_{\text{target}}$ , then compressed and decoded to reconstruct the scene. This enables multiple operating points and a continuous rate–distortion curve from a single trained model.

prune Gaussians, thereby reducing the overall representation size [2]. However, most existing methods operate at fixed compression rates [10, 11, 12, 13], which limits their adaptability to different application requirements, such as variable bandwidth and device capabilities. This rigidity limits the practical deployment of 3DGS across various real-world scenarios, where dynamic trade-offs between quality, storage, and computation are often required in real-time.

In this paper, we tackle this issue by proposing RAVE, a rate-adaptive model-agnostic method that enables flexible compression of 3D Gaussian Splatting representations. Unlike previous approaches, RAVE supports interpolation at any rate within a specified range, yielding a fine-grained control over the rate-distortion trade-off through predefined contexts (Fig. 1). With marginal extra costs in training (in terms of learning iterations), our method is the *first to allow dynamic rate adaptation without retraining*. Notably, achieving such flexibility is not straightforward. Indeed, naïve solutions tend to either markedly degrade quality or impose significant computational overhead.

## 2. RATE-ADAPTIVE GAUSSIAN SPLATTING

### 2.1. Preliminaries

3D Gaussian Splatting (3DGS) [4] has emerged as a state-of-the-art method for real-time radiance field rendering, combining high image quality with exceptional rendering speed. In this approach, a scene is represented by a set of volumetric Gaussian primitives, each defined by a position  $x$ , a covariance matrix  $\Sigma$  (decomposed into scale and rotation components), an opacity  $o$ , and a set of Spherical Harmonics (SH) coefficients that encode view-dependent color or appearance. During the rendering stage, 3D Gaussians are projected into the 2D image plane and alpha-blended. Blending weights for

a given projected point are computed as:

$$\alpha(x) = o \cdot G(x), \quad \text{with} \quad G(x) = \exp\left(-\frac{1}{2}x^T \Sigma^{-1}x\right) \quad (1)$$

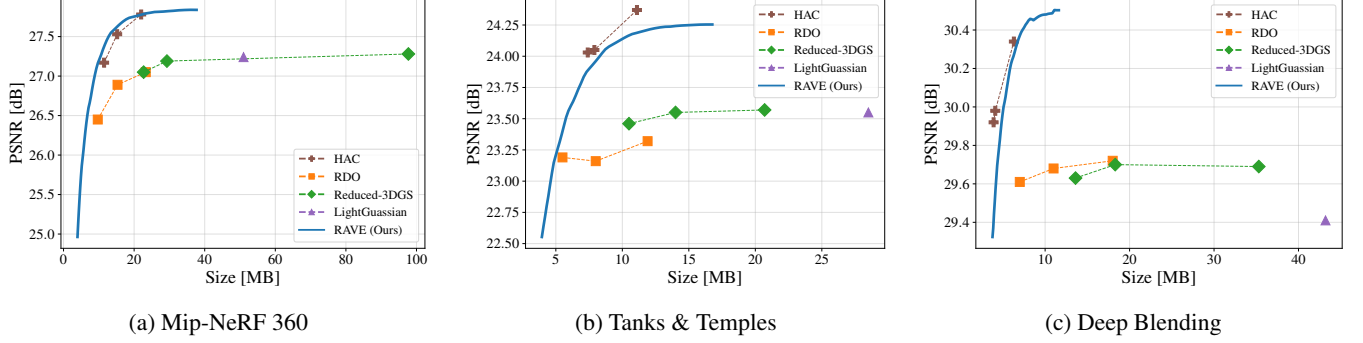

representing the Gaussian contribution at position  $x$ . The SH coefficients are evaluated to produce color values specific to the current view, and the combination of these colors through alpha compositing reconstructs the final appearance of the scene. The initial set of Gaussian primitives is derived from a sparse Structure-from-Motion (SfM) point cloud, providing a coarse scene initialization. These parameters are then optimized through gradient descent, while simultaneously performing adaptive refinement operations that split, merge, or adjust the primitives to better match the underlying geometry. The optimization jointly minimizes pixel-wise reconstruction error and structural similarity loss.

### 2.2. Training for variable rate transmission

Taking inspiration from the literature on Level of Details for 3DGS [14], we can introduce a variable-rate approach by defining anchor points at  $L$  fixed rate-distortion levels. Starting from a pre-trained model, a hierarchy of gradient-based masks can be generated to progressively select subsets of Gaussians. Formally, the hierarchy is defined as

$$\mathcal{G}_l = \bigcup_{i=1}^l \mathcal{C}_i, \quad (2)$$

where  $\mathcal{G}_l$  groups Gaussians from the lowest rate anchor to  $l-1$ , and  $\mathcal{C}_l$  represents the Gaussians to be introduced to move from anchor  $l-1$  to  $l$ , representing our *context*. The Gaussians hierarchy is established by defining a rate delta  $\Delta\mathcal{R}$  that translates to a fraction of Gaussians to be added/removed to

**Fig. 3:** Comparison of RAVE against state-of-the-art compression methods. Notably, our method is the only one that allows for a continuous rate without requiring any retraining. The results are competitive, achieving state-of-the-art performance on Mip-NeRF360. All other methods require a separate training run for each point on the curve.

move from anchor  $l-1$  to  $l$ , and their ranking is defined based on the gradient calculated on the training set.

After building the hierarchy, we can perform quantization-aware fine-tuning using stochastic mask sampling: this means that, with uniform probability, we choose to optimize either of the  $L$  anchor points.

After fine-tuning, we can easily interpolate between various anchors  $l-1$  to  $l$  re-estimating the gradient on the subset  $\mathcal{C}_l$ : leveraging the principle of locality, we know that the denser the anchors for the same bitrate regime, the more accurate the gradient-based ranking. Therefore, given  $\mathcal{R}(\mathcal{G}_l)$  the rate for  $\mathcal{G}_l$ , the number of Gaussians for a specific bitrate  $\mathcal{R}^{\text{target}}$ , for which  $l = \text{argmax}\{\mathcal{R}(\mathcal{G}_l) \leq \mathcal{R}^{\text{target}}\}$ , will be

$$|\mathcal{G}_{\text{target}}| = |\mathcal{G}_l| + \frac{\mathcal{R}^{\text{target}} - \mathcal{R}(\mathcal{G}_l)}{\mathcal{R}(\mathcal{G}_{l+1}) - \mathcal{R}(\mathcal{G}_l)} (|\mathcal{G}_{l+1}| - |\mathcal{G}_l|). \quad (3)$$

Among the budget  $|\Delta\mathcal{G}| = |\mathcal{G}_{\text{target}}| - |\mathcal{G}_l|$ , we select the Gaussians having the highest gradient, extracted from the context  $\mathcal{C}_{l+1}$ :

$$\Delta\mathcal{G} = \bigcup_{i=1}^{|\Delta\mathcal{G}|} G_i \left| G_i \in \mathcal{C}_{l+1}, \left\| \frac{\partial \mathcal{L}}{\partial \theta_i} \right\|_2 \leq \left\| \frac{\partial \mathcal{L}}{\partial \theta_j} \right\|_2 \forall i < j, \right. \quad (4)$$

where  $\theta$  represents the parameter of the Gaussian and  $\mathcal{L}$  is the rendering loss function. The gradients are calculated only once on the training set.

### 2.3. Method overview

In Fig. 2, we present an overview of our method. Our objective is to generate high-quality scene reconstructions at an arbitrary target rate  $\mathcal{R}^{\text{target}}$ , determined by constraints such as network bandwidth, storage budget, or hardware capabilities, without requiring additional training or model fine-tuning. We start by considering a set of Gaussians  $\mathcal{G}_l$  produced at a given anchor level, together with its local context  $\mathcal{C}_{l+1}$ . Each anchor acts as a local reference, restricting the optimization to a well-defined subset of Gaussians and allowing

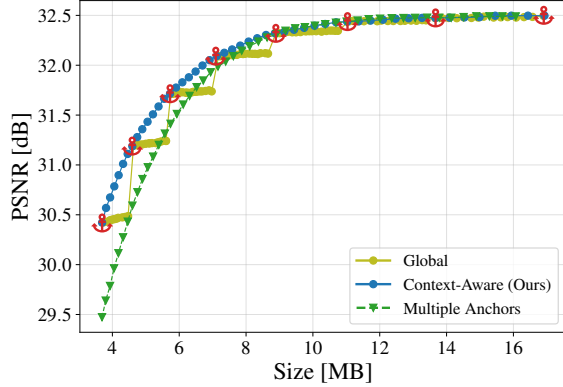

for efficient computation. For each Gaussian, we compute an importance score by accumulating its gradient over a single forward pass through the training set. This operation is performed only once per anchor level and provides a stable ranking of Gaussians based on their contribution to reconstruction quality. Given a target rate  $\mathcal{R}^{\text{target}}$ , we identify the anchor level that contains the desired number of Gaussians and select the top-ranked ones until the rate budget is satisfied, producing a subset  $\mathcal{G}_{\text{target}}$ . Crucially, since the ranking is precomputed, this selection process can be repeated for any number of target rates  $\mathcal{R}^{\text{target}_1}, \mathcal{R}^{\text{target}_2}, \dots$  efficiently and without recomputing gradients, enabling the generation of multiple rate-quality operating points from a single trained model. Finally, the parameters of the selected Gaussians are compressed using entropy coding (LZMA in our implementation, chosen for its strong compression ratio and practical speed), transmitted, and decoded at the receiver side to reconstruct the scene. Because our method is codec-agnostic, different compression backends could be substituted with no modification to the overall pipeline. This design allows us to generate an entire continuous rate-distortion curve from a single training run, supporting smooth adaptation to bandwidth or storage constraints at inference time.

## 3. EXPERIMENTS

### 3.1. Setup

We evaluated our method on the three major benchmarks for 3D Gaussian Splatting: Mip-NeRF360 [15], Tanks&Temples [16], and DeepBlending [17]. These datasets cover diverse real-world scenarios and provide challenging conditions for assessing reconstruction quality and generalization. For the 3DGS model, we adopt Scaffold-GS [18] as our backbone architecture.

To perform Gaussian selection, we compute the gradient with respect to the  $\mathcal{L}_1$  loss over rendered pixels combined with an SSIM term  $\mathcal{L}_{\text{SSIM}}$  as in the standard 3DGS-based methods.

**Fig. 4:** Comparison with a global variant of our method, where the gradient is computed globally before each pruning stage, and with a naïve multi-anchors strategy (50 levels). Our method highlights the importance of context, while at the same time being superior to multi-anchor strategy.

The final rendering loss is given by:

$$\mathcal{L} = (1 - \lambda)\mathcal{L}_1 + \lambda\mathcal{L}_{\text{SSIM}}, \quad (5)$$

where  $\lambda$  is a unit interval ratio hyperparameter set to 0.2 in our experiments.

### 3.2. Main results

As shown in Fig. 3, our method achieves competitive performance compared to the most recent compression techniques for 3DGS. Notably, it is the only approach that supports continuous variable rate compression, whereas all other non-scalable and non-continuous methods require separate, ad hoc training runs to obtain each point on the rate–distortion curve. This process is very expensive and not feasible in practice, where we often need to adapt the rate to specific constraints. More specifically, our method reaches state-of-the-art performance on Mip-NeRF360, slightly outperforming HAC, while still being competitive on the other datasets. This result is particularly noteworthy given that our approach jointly optimizes for a single, continuous variable rate model rather than training multiple models for different rates.

### 3.3. Variable rate transmission is not easy

**Global vs Context-Aware.** To better understand the role of the interpolation strategy, we consider two distinct approaches. In the first case, the ordering of the newly introduced Gaussians (those present in level  $l + 1$  but not in level  $l$ ) is derived from gradients computed with respect to the *global* scene, *i.e.*, the reconstruction in which all Gaussians up to the highest-rate anchor are included. With this global context, however, the ranking is dominated by structures that only become relevant at higher rates, which results in poorly

aligned intermediate reconstructions. Fig. 4 shows the result obtained in the scene “room” of the Mip-NeRF360 [15] benchmark. Here, the RD curve obtained in this way exhibits irregularities, thus preventing a smooth transition between the anchors at different levels. In our approach, instead, we compute the gradient in a local context, restricting the rendering to the Gaussians of level  $l + 1$  only. This subtle change is crucial, as it ensures that the ranking reflects the contribution of the Gaussians added at that specific stage of the interpolation. Consequently, the intermediate models evolve more coherently from one anchor to the next one, and the resulting RD curve becomes smooth and continuous. This validates our design choice: by focusing the gradient computation on the relevant local context, we enable dynamic rate adaptation without quality loss along the interpolation path.

**Multiple anchors.** We also compare our approach against a naïve strategy (green curve in Fig. 4), which attempts to approximate a continuous RD curve by defining an arbitrary number of anchors. In principle, with this simple strategy, we can densely populate the rate axis. However, this comes at a significant computational cost. Indeed, for each anchor, it is necessary to compute a new ordering of the Gaussians based on gradient evaluation. As the number of levels increases, this calculation becomes significantly expensive, thereby making this strategy impractical for real-world applications.

Moreover, as shown in Fig. 4, increasing the number of levels (*e.g.*, up to 50 in our experiment) directly affects the RD behavior, obtaining worse results than in the case where fewer anchors are considered. This highlights a structural limitation of such an approach: while it can, in principle, approximate continuity by brute force, it becomes both inefficient and unstable when the number of anchors grows. In contrast, our approach achieves a truly continuous RD curve with far fewer models, while being faster, more lightweight, and consistently yielding higher quality reconstructions.

## 4. CONCLUSION

We presented a flexible compression framework for 3D Gaussian Splatting that allows continuous interpolation between compression rates while maintaining efficient rendering and competitive visual quality. Unlike existing approaches constrained to fixed-rate operation, our method adapts seamlessly to diverse computational and bandwidth conditions, enabling practical deployment in immersive multimedia scenarios. The results show that high-quality rendering can be preserved across a wide range of operating points at minimal computational cost, demonstrating that adaptive compression of 3DGS is both feasible and effective. This opens the door to more versatile scene representations that can dynamically respond to application requirements, paving the way toward scalable, interactive, and resource-aware immersive experiences.
