This paper attempts a first analysis of citation distributions based on the genderedness of authors' first name. Following the extraction of first name and sex data from all human entity triplets contained in Wikidata, a first name genderedness table is first created based on compiled sex frequencies, then merged with bibliometric data from eponymous, US-affiliated authors. Comparisons of various cumulative distributions show that citation concentrations fluctuations are highest at the opposite ends of the genderedness spectrum, as authors with very feminine and masculine first names respectively get a lower and higher share of citations for every article published, irrespective of their contribution role.

1. Introduction

Following initiatives carried out in biomedical and feminist research in the late 1960s and 1970s, the concept of gender has a clear semantic scope, distinct from that of sex: while the latter and its related attributes of maleness and femaleness refer to everything that is biologically-driven, the concepts of gender, masculinity, and femininity refer instead to the self-identify and to the culturally-determined behavioural and psychological traits that form the social representation of an individual (Torgrimson, 2005; West & Zimmerman, 1987; Reisner et al., 2015; Ansara & Hegarty, 2014). More generally, the concept of gender came to refer to all the subjective aspects surrounding the concreteness and objectivity of sexually-determined features. Despite this clear conceptual divide, however, scientific research often reduces gender to sex. In social science for example, participants are often asked to disclose their gender by choosing between only two possible answers, namely those historically and conceptually associated with sex: 'male' and 'female' (Westbrook & Saperstein, 2015). Regardless of the intent, this dichotomization of a concept "not at all limited to two kinds" (Walker, 1998: 255-256) has the unfortunate consequence of sweeping under the carpet "what the researchers are aiming at and what participants respond to - bodily attributes, legal, gender, or self-defined gender identity (Lindqvist, 2021: 334)".

In science studies, while a great deal of research effort has been aimed at highlighting gender disparities within the scientific community (Sugimoto & Larivière, 2023), most of it is based on the use of automatic procedures whose goal is to determine, from the first name of individuals, whether they are male or female (Gonzalez-Salmón et al., 2024; Halevi, 2019). Unquestionably useful in debunking various forms of inequalities in science, this operational

dichotomisation however overlooks the defining feature of gender, what distinguishes it conceptually from sex: subjectivity. For many activities of crucial importance to the scholarly community, whether authors are actually male or female might not matter as much as how they perceive themselves or are perceived by the readers. And since first names are often the only information available to readers for identification purposes, many disparities attributed by the field to a sexually dichotomised conception of gender, could very well stem from the genderedness of authors' first names, that is, from how masculine or feminine their first name is. Such a perspective, strongly reminiscent of the idea that "masculinity and femininity do not exist 'out there' in the world of objective realities... [but] only in the mind of the perceiver" (Bem 1987, 309), is the anchor point of this project, whose aim is to attempt a first analysis of citation distributions based on the genderedness of authors' first names. Following a short overview on the psychological and social aspects of the relationship between names and gender, the process behind the construction of the first name genderedness database and bibliometric database used in this project is then presented, after which citation analysis results are analyzed.

1. The Impact of Name and Gender

Naming humans has a profound impact on individuals and society in general. Research shows that many first name features do a good job of predicting social variables, even when controlling for other background factors such as race, gender, parents' education levels, age, and siblings (Aura and Hess, 2004, 2010). Names thus carry a lot of information about personal characteristics, information which shapes not only how a person perceives herself or himself, but also how she or he is perceived by others and how she interacts with them (Figlio, 2005).

Of the various signals names can give to oneself and to others, gender certainly figures amongst the most prominent ones. While some languages and cultures use personal names to sex individuals, most of them name individuals in a relatively gendered way, depending on how masculine or feminine a given name is to a given culture at a given point in time. In English, first names like 'Jill' and 'Bill' are strongly associated with female and male individuals respectively (Bauer and Coyne 1997; Nick 2017), while some like 'Lee' defy easy gender categorization (van Fleet and Atwater 1997). The genderedness of names can also change over time, as with 'Leslie' (Blevins and Mullen, 2015), or even across countries, 'Andrea' perhaps being the most famous case (Vasilescu et al., 2014; West et al., 2013). In fact, all first names unfold and move within a vast genderedness spectrum ranging from the most feminine first names to the most masculine ones. Any subtle variation in spelling can result in wide shifts in genderedness: "a woman could have a traditionally male name (such as 'Patrick'), an ambiguous name ('Pat'), or a typically female name ('Patricia'). A continuous spectrum of possibilities ranges between these points; something like 'Patric' might be mostly male but less certainly so than is 'Patrick'" (Urbatsch, 2018: 59). And every time a newly born baby is given a name, something changes in the genderedness spectrum.

Research has shown that focusing on the masculinity or femininity of first names allows to explain phenomena and account for behavioral patterns that a sex-based dichotomy cannot. For instance, studies based on the Portia hypothesis show that female lawyers with more masculine names have better chances of being hired, have higher salaries, and are more likely to become judges (Coffey and McLaughlin, 2016, 2009). Various studies have observed similar effects on hiring for musical (Goldin and Rouse, 2000), psychological (Steinpreis et al., 1999), and STEM professions (Moss-Racusin et al. 2012) as well as in state-legislative elections in the United States (Urbatsch, 2018). From a developmental perspective, it was also shown that boys with female-sounding names tend to misbehave disproportionately upon entry to middle school; in the same vein, a study focusing on pairs of highly-achieving sisters found that femininely-named girls tend to be as successful as their less femininely-named sisters in mathematics, but

are however less likely to select the most advanced mathematics and science courses in high school (Figlio, 2005, 2007).

Within the field of science studies, two projects focused on the impact of perceived gender, based on journal editors' assessments of authors' first names, on publication acceptance rates: the first study has shown that one of five ecology and evolution journals showed an acceptance bias against submitters with feminine names (Tregenza, 2002), while the second discovered that the establishment of a double-blind reviewing process in a primary research journal resulted in increased acceptance rates for authors with feminine first names (Budden et al. 2008). In order to pursue and encourage this subjective turn in the study of gender disparities in science, the current project aims to establish a kind of proof of concept, aimed at isolating and analysing the subjective, perceptual component of gender disparities in citation counts.

2. Methodology

The different data sets used for the analyses below were obtained through a series of data collection and processing procedures implemented in Python. All gender-related data used in this research has been extracted from semantic triples contained in the Wikidata knowledge base. Following the download of the latest truthy (i.e. most up-to-date and failsafe) data dump on April 3rd 2024, all Wikidata semantic triples having human-specific entities as subjects and given name (P735), male (Q6581097), or female (Q6581072) as objects were extracted from the data. Following this, first names were converted to ASCII encoding format using the Python **Unidecode** package <https://github.com/avian2/unidecode>, and all entities extracted were merged using semantic triplet subjects as keys, resulting in a total of 65,263 unique first names spread across 7 807 233 human entities. Finally, a gender frequency table was generated by compiling the frequency of male and female entities for each distinct first name.

As regards to bibliometric data, author first names, roles, and article citation counts were extracted from the Web of Science Core Collection. In order to control for cultural, national, and historical factors, only articles, notes, and reviews published between 2010 and 2019 by authors affiliated to American institutions were considered for this study. Five different subsets were collected, depending on the following publication roles of authors: single author (62,768 unique first names over 386,274 documents), first author (329,670 unique first names over 3,696,564 documents), middle author (621,322 unique first names over 15,246,000 documents), last author (215,252 first names over 3,696,564 documents), and corresponding author (383,429 unique first names over 5,882,797 documents) (where corresponding author info was absent, single authors or first authors were also considered corresponding authors by default).

Following this, first names in both datasets were harmonized through a series of pre-processing operations. All non-word characters were replaced with single whitespaces, and substrings of whitespaces were reduced to single whitespaces. To remove initials, all first names were stripped of single letters and substrings of consecutive upper-cased letters (to cover the case of initials without punctuation). Following this, all first names were then converted to lower case, and data points which had their first name information deleted because of the previous operations were removed from both datasets. Data from the Wikidata gender frequency table was then added to the citation data set in a two-step procedure. Frequencies were first collected by merging both datasets using cleaned first names in both data sets as keys. Given that the Web of Science often includes middle names at the end of authors' first names, a second merging procedure was implemented, using the first element of all compound first names from the article data set as merging key. Outputs from both merging operations were then concatenated together and gender frequencies of first names present in both merged sets summed up. As a result of these various operations, article and citation counts was obtained and compiled for a total of 81,561 first names appearing at least once in one or more of the

following author dataset: first (17,352 first names, 2,255,418 articles, and 261,970,776 citations), corresponding (18,363 first names, 3,706,433 articles, and 417,492,008 citations), middle (21,997 first names, 8,990,326 articles, and 13,970,659,493 citations), last (15,504 first names, 2,476,159 articles, and 250,343,014 citations), and single (8,345 first names, 292,020 articles, and 5,021,177 citations).

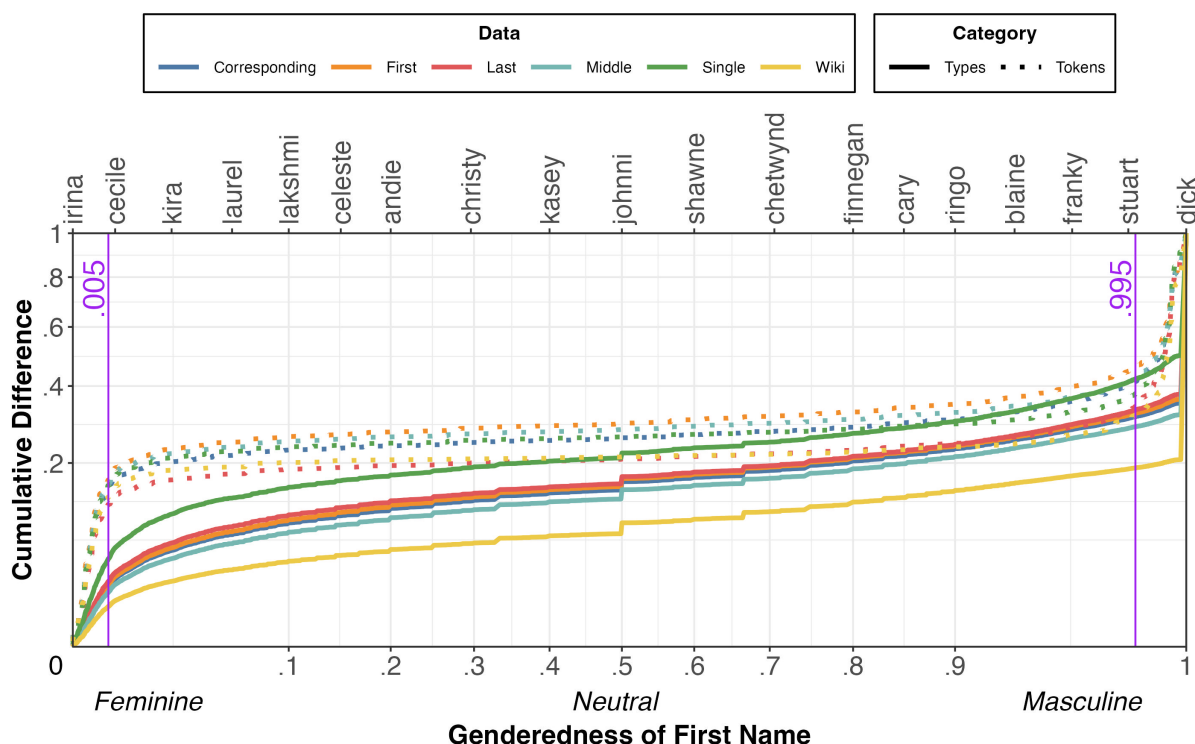

Following this harmonization of first names, first name genderedness was obtained by dividing the male frequency associated with a first name by its corresponding total frequency. The result of this operation can be interpreted as the relative frequency-based probability that a given first name refers to a man: a probability of 1 means that the person bearing that first name is assuredly a man, as no female entity with that first name has been found in Wikidata; inversely, a low probability means that the corresponding first name most probably refers to a woman, most Wikidata entities bearing that name having been registered as female. Once these probability values were compiled, article and citation counts were summed up for each distinct genderedness value between 0 and 1.

3. Results

First name distributions extracted from all data sets were first analyzed using the distinction between tokens and types, which respectively refer in lexical context to the total number of words and the number of different words in a language sample (Peirce, 1906). Interpreted within the frame of the gender continuum, the number of types found at a specific point of the continuum refers to the number of unique first name whose genderedness score corresponds to that value, while the token count at the same point along the continuum corresponds to the total occurrences of these unique first names in the corresponding database. The meaning of the relationship between types and tokens is however very different depending on the dataset considered. In the case of Wikidata, token and type frequencies correspond respectively to the diversity and popularity of human entities' first names at a given point of the genderedness spectrum. Given the nature of data collected in the different WoS datasets, however, the first name types and tokens found therein are those of authors, which means that their relationship carries important information as regards to productivity in general as well as to the impact of first name genderedness thereon. Indeed, for the different author type categories considered here, the higher the proportion of tokens to types at a given point of the genderedness spectrum is, the more articles the authors whose first names are of equal and corresponding genderedness value publish. While the number of authors whose first names are found at a specific point of the genderedness continuum is unknown, the productivity information conveyed here can nonetheless be useful in comparing the different author type distributions as well as in the citation analysis that follows.

The cumulative distributions shown in figure 1 correspond to the fluctuations in type and token counts along the genderedness spectrum for the different datasets analyzed in this study. First names were added at each tick mark along the x axis to serve as interpretative aids. As can be seen from these examples, the closer the genderedness score of a first name is to 0 and 1, the more feminine and masculine that name is respectively. In addition, the closer a first name is to the midpoint of the genderedness continuum (0.5), the more gender-neutral or gender-ambiguous (and often less stereotypical or common) it is, and thus the harder the task of identifying the gender of someone on a first name basis. Finally, the x- and y-axes were respectively rescaled using arcsine and square root transformations in order to highlight the most salient features of the different distributions near the lower and upper bounds of the genderedness spectrum.

Figure 1: Cumulative distribution of first name tokens and types along the genderedness continuum, grouped by data type.

As can be seen from the outset, cumulative distributions are far from uniform: for both types and tokens, the 1% of the most gendered first names (those with a genderedness score lower than 0.005 or higher than 0.995) account for at least half of all first names contained in each dataset. In the case of type distributions, most of that concentration lies near the upper bound of the spectrum, which means very masculine first names account for most first name diversity in all datasets. This asymmetry is especially strong in the case of Wikidata, as close to 80% of all unique first names have a genderedness score of 0.9999 or higher, concentration which not only resonates with previous research on the matter (Konieczny and Klein 2018; Tripodi, 2023), but also shows that the different first names included in the author type datasets are not as strongly masculine as those from which their genderedness score were computed. This lower concentration is due to a higher diversity of very feminine first names, especially in the case of the single author distribution.

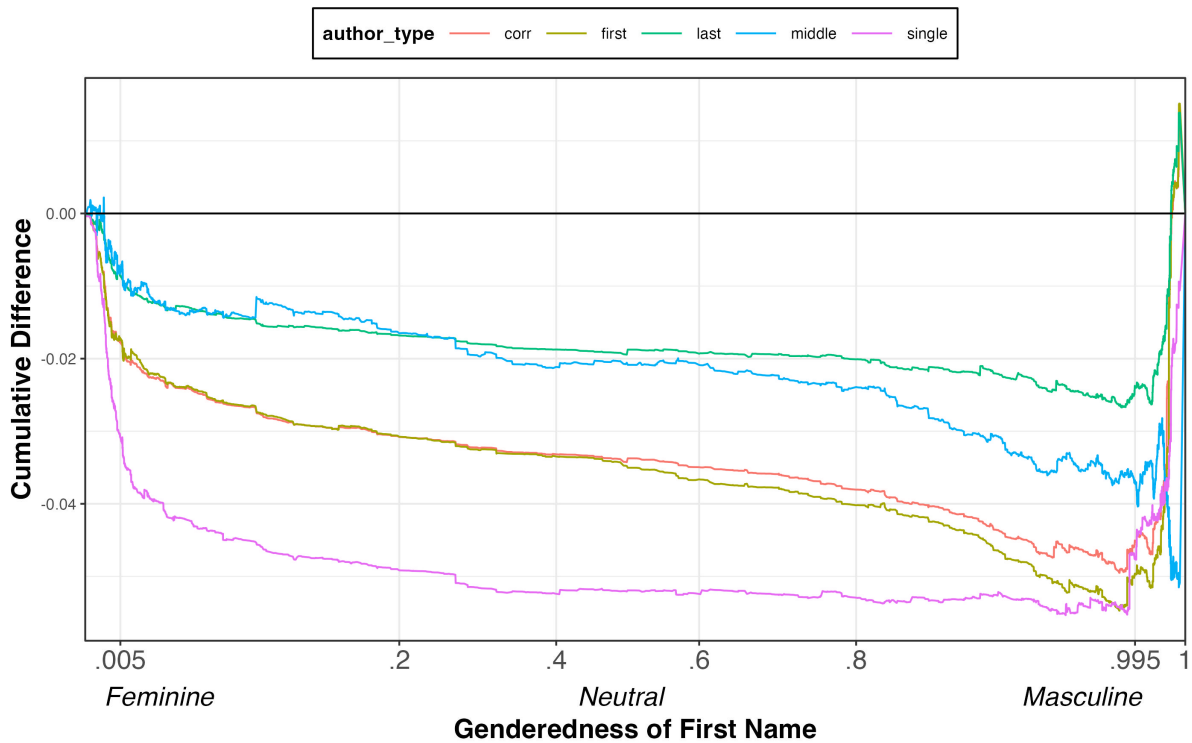

As for the different token distributions, cumulative concentration along the genderedness spectrum is relatively the same across all datasets. Such uniformity means that the respectively lower and higher diversities of very female first names found in the Wikidata and single author datasets are somehow neutralized by counteracting token fluctuations, namely through a higher and lower relative popularity of very female first names, in that order. But generally and perhaps more importantly, token distributions all have a higher cumulative concentration at the feminine end of the genderedness spectrum, which implies that very feminine first names are less diverse in all datasets, but that the first names included in that relatively smaller set tend to occur more often than the first names found elsewhere on the spectrum.

As regards finally to scholarly production, tendencies are similar across author types: around 75% of articles published in the US between 2010 and 2019 have been authored by authors whose first names are amongst the 1% most gendered ones, and more than half of all articles have been published by very-masculinely-named authors. These cumulative trends in scholarly productivity are especially relevant here, as they allow for a finer-grained analysis of

concentration fluctuations in citation counts across the genderedness spectrum. Indeed, subtracting the cumulative first name token distribution of each author type dataset to the corresponding cumulative citation distribution allows to control for author productivity in analyzing concentration fluctuations in citation counts across the genderedness spectrum for the different author types.

Following these computations, positive and negative cumulative differences indicate that the cumulative citation distribution is respectively larger and smaller at the corresponding point of the genderedness spectrum than its article counterpart. Perhaps more importantly, an increase or decrease in the difference slope indicates a corresponding fluctuation in citation concentration at that specific point of the genderedness continuum, which means that authors located at this point of the spectrum get a relatively lower share of citations, regardless of how productive they are. Finally, cumulative differences are null at both extremities of the genderedness spectrum, as the relative cumulative sums for both article and citation distributions at these points are both 0 and 1. The cumulative difference plot included in Figure 2 shows these fluctuations in citation concentration across the genderedness continuum for the different author types.

Figure 2: Cumulative difference between citations and articles, grouped by author type.

Overall, all cumulative difference distributions follow the same general pattern, characterized by a sudden drop at the feminine end of the continuum, followed by a long and slow downward slope that extends to the very masculine end of the genderedness spectrum, where acute spikes in citation concentration brings the slope back to zero or above. In other words, authors whose first names are not very masculine, especially those that have very feminine first names, get a lower share of citations, regardless of their productivity or authorship type. Beyond these general trends, some differences can however be observed between the author type distributions. The drop in citation concentration in the feminine end of the genderedness spectrum is the strongest in the case of single authors, where the genderedness of an authors' first name is not counterbalanced by that of any co-authors, and smallest in the case of middle

and last authors, whose first names do not arguably attract as much attention. At the other end of the spectrum, first, corresponding, and last authors with very masculine first names get a relatively, yet markedly higher citation share than authors elsewhere in the genderedness spectrum. And given that these fluctuations relate to differences in cumulative counts between citations and articles, it is safe to conclude that the higher and lower citation concentrations observed respectively at the masculine and feminine ends of the genderedness spectrum are completely independent of productivity. In other words, an article published by an author with a very masculine first name will tend to get more citations, especially if published as first, last or corresponding author, while an article written by an author with feminine first name will get relatively less cited, even more so if that author publishes it alone.

Viewed as such, the results presented here provide interesting insights to certainly resonate., refers to a systematic bias against women in various aspects of scientific practice (Rossiter, 1993).

Interpreted within the framework of the Matilda effect (Rossiter, 1993), these results provide interesting insights on the relationship between scholarly gender and the academic reward system. First, it shows that gender, as operationalized through the masculinity and femininity of authors' first names, represent a more than viable tool for the analysis of distributional asymmetries in citation counts, independently from sex. But perhaps more importantly, this project shows that in the context of citation practices, the domain of the Matilda effect lies at the extreme ends of the first name genderedness continuum: regardless of sex, productivity or contribution type, citation unbalances almost exclusively affect authors whose first names are the most gendered, with femininely-name and masculinely-named authors respectively getting the short and long ends of the reward stick. Certain caveats should however be noted when interpreting these results. First, the concept of gender is here approached from a purely agnostic perspective (Figlio 2007), based on observed frequencies; any further theoretical consideration pertaining to gender would take the project beyond what is afforded by the data used. Furthermore, given its descriptive nature, the current project cannot in any way prove or hint at the existence of a causal effect of gender on citations; in this sense, the gender differences highlighted here do not constitute sufficient grounds for any bias claim (Traag and Waltman, 2022). In the same vein, the trends observed here represent macrobehaviors and as such do not warrant any claim regarding individual micromotives; any attempt to do so must be met with the greatest skepticism (Schelling, 2006). Beyond these limitations, however, it is hoped that the results presented here contribute to bring new impetus and perspectives to the study of gender disparities in science.

Open science practices

All gender-related data used in this research has been extracted from semantic triples contained in the Wikidata knowledge base, whose “truthy” and complete data dumps are freely available at <https://dumps.wikimedia.org/wikidatawiki/entities/>.
