

A Class of Axis–Angle Attitude Control Laws for Rotational Systems

Francisco M. F. R. Gonçalves, Ryan M. Bena, and Néstor O. Pérez-Arancibia

Abstract—We introduce a new class of attitude control laws for rotational systems, which generalizes the use of the Euler axis–angle representation beyond quaternion-based formulations. Using basic Lyapunov’s stability theory and the notion of extended \mathcal{K}_∞ functions, we developed a method for determining and enforcing the global asymptotic stability of the single fixed point of the resulting *closed-loop* (CL) scheme. In contrast with traditional quaternion-based methods, the proposed generalized axis–angle approach enables greater flexibility in the design of the control law, which is of great utility when employed in combination with a switching scheme whose transition state depends on the angular velocity of the controlled rotational system. Through simulation and real-time experimental results, we demonstrate the effectiveness of the proposed approach. According to the recorded data, in the execution of high-speed tumble-recovery maneuvers, the new method consistently achieves shorter stabilization times and requires lower control effort relative to those corresponding to the quaternion-based and geometric-control methods used as benchmarks.

Index Terms—Axis–Angle, Attitude Control, Robotics.

I. INTRODUCTION

NUMEROUS different types of attitude controllers have been thus far proposed for stabilizing and commanding the trajectory of rotational systems that can be modeled as rigid bodies [1]–[16]. These controllers can be classified into three main types: (i) quaternion-based, (ii) Euler-angles-based, and (iii) rotation-matrix-based (geometric). The limitations of attitude controllers based on Euler angles have been extensively studied and discussed in the technical literature—for example, see [17] and references therein. For this reason, quaternion-based and geometric methods have been the preferred choices for implementing robust high-performance attitude controllers. Although these two attitude representations implicitly contain the knowledge about the Euler axis and associated rotation angle as defined in [18], this information is generally not directly used in the design of attitude controllers.

For example, quaternion-based time-invariant attitude control laws, usually include a proportional term that is formed

by scaling the attitude-error Euler axis with $\sin \frac{\Theta_e}{2}$, where Θ_e is the corresponding instantaneous rotation error. However, there is not a reason for this type of formulation other than ensure continuity in the entire rotational space and simplify the analysis of the resulting *closed-loop* (CL) system. Counterintuitively, however, in most practical applications, this continuous control law is modified to obtain a switching or hybrid scheme to avoid unwinding behavior [4]–[8]. Another consequence of implementing continuous quaternion-based control laws is that, for rotational errors larger than π rad, the proportional-control effort decreases as the rotational error about the attitude-error Euler axis increases. In a similar fashion, geometric-based attitude control laws implicitly apply torques in the direction of the shorter rotational trajectory required to eliminate the attitude error. As discussed in [1] and [2], this direction choice is not necessarily the best for every kinematic situation, depending on the specific performance objectives of the problem of interest.

In this letter, we introduce a class of attitude control laws applicable to a wide gamut of rotational systems that can be modeled as rigid bodies moving in the *three-dimensional* (3D) space, including *uncrewed aerial vehicles* (UAVs), satellites, and microrobotic swimmers. The proposed method generalizes the use of the Euler axis–angle representation in the formulation of the feedback law that stabilizes and drives the rotational motion of the controlled system. It is widely known that global asymptotic stability in the 3D rotational space cannot be achieved with the use of continuous time-invariant feedback controllers. Nonetheless, a common technique used to overcome this topological obstruction is to design discontinuous control laws [8]. Following this approach, by combining Lyapunov’s stability theory and the notion of extended \mathcal{K}_∞ functions, we developed a method that ensures the existence of a unique CL fixed *attitude-error quaternion* (AEQ) and the global asymptotic stability of the corresponding equilibrium point, which depends on a positive-definiteness condition that the controller gains must satisfy.

A main contribution of the work presented in this letter is the design flexibility enabled by a generalized formulation of the proportional term in the proposed control law; specifically, it allows the user to select a suitable proportional control function based on the platform and/or application, with stability guarantees. Furthermore, in contrast to existing quaternion-based control methods, the new generalized axis–angle attitude control approach ensures a greater proportional action the farther away the system’s state is from the stable CL equilibrium AEQ. This characteristic is especially useful when a scheme of the proposed type is employed in combination with intelligent switching methods capable

of taking into account the angular velocity when selecting the direction in which the input torque is applied during operation, as for example done in the case presented in [1]. We tested the functionality and performance of the introduced approach through simulations and outdoor flight tests. The obtained simulation and experimental data show that compared to two other high-performance benchmark controllers—one quaternion-based and another geometric—a scheme of the new type is unequivocally superior. Specifically, data obtained through dozens of high-speed tumble-recovery maneuvers show that the new approach consistently achieves shorter stabilization times and requires less control effort, from a statistical standpoint. Due to space constraints, in this letter, we limit the discussion to the attitude control problem; however, a position control scheme of the type presented in [4] can be straightforwardly integrated with the presented method for attitude control.

Notation—

- 1) Lowercase symbols represent scalars, e.g., p ; bold lowercase symbols denote vectors, e.g., \mathbf{p} ; bold uppercase symbols denote matrices, e.g., \mathbf{P} ; and bold crossed lowercase symbols denote quaternions, e.g., \mathbf{p} .
- 2) The set of unit vectors is denoted by \mathcal{S}^2 . The special orthogonal group in the three-dimensional space is denoted by $SO(3)$.
- 3) The sets of reals and positive reals are denoted by \mathbb{R} and $\mathbb{R}_{>0}$, respectively. The set of integers is denoted by \mathbb{Z} .
- 4) The symbols \times and \otimes respectively denote the cross-product of two vectors and the multiplication between two quaternions.
- 5) Throughout the rest of the paper, we use the notion of extended class \mathcal{K}_∞ function as defined in [19].

II. BACKGROUND

We first describe the dynamics of a rigid body rotating in the 3D space. As shown in Fig. 1, $\mathcal{B} = \{\mathbf{b}_1, \mathbf{b}_2, \mathbf{b}_3\}$ denotes the body-fixed frame of reference, with its origin coinciding with the body's *center of mass* (CoM), used for kinematic description and dynamic analysis. Consistent with this definition, $\mathcal{I} = \{\mathbf{i}_1, \mathbf{i}_2, \mathbf{i}_3\}$ denotes the inertial frame of reference, fixed to the planet, used for formulation and analysis. As discussed in [4], [5], using quaternions and Euler's second law, the open-loop rotational dynamics of the system can be described according to

$$\dot{\mathbf{q}} = \frac{1}{2} \mathbf{q} \otimes \begin{bmatrix} 0 \\ \boldsymbol{\omega} \end{bmatrix}, \quad (1a)$$

$$\dot{\boldsymbol{\omega}} = \mathbf{J}^{-1} (\boldsymbol{\tau} - \boldsymbol{\omega} \times \mathbf{J} \boldsymbol{\omega}), \quad (1b)$$

in which \mathbf{q} is a unit quaternion that represents the orientation of \mathcal{B} relative to \mathcal{I} ; $\boldsymbol{\omega}$ is the angular velocity of \mathcal{B} with respect to \mathcal{I} , written in \mathcal{B} coordinates; \mathbf{J} is the inertia matrix of the body, written in \mathcal{B} coordinates; and, $\boldsymbol{\tau}$ is the torque applied to the system written in \mathcal{B} coordinates and, in closed loop, generated by a control law.

As specified by Euler's rotation theorem, any sequence of rotations of a rigid body in the 3D space is equivalent to a single rotation of amount Θ about an axis \mathbf{u} that passes through the body's CoM. This information can be stored in the form of a unit quaternion as $\mathbf{q} = [m \ \mathbf{n}^T]^T$, where

Fig. 1. Picture of the UAV used in the flight control experiments. The Crazyflie 2.1 quadrotor and the definitions of the inertial frame of reference, $\mathcal{I} = \{\mathbf{i}_1, \mathbf{i}_2, \mathbf{i}_3\}$, fixed to the planet and the body-fixed frame of reference, $\mathcal{B} = \{\mathbf{b}_1, \mathbf{b}_2, \mathbf{b}_3\}$ (shifted for clarity), whose origin is attached to the center of mass of the robot.

$m = \cos \frac{\Theta}{2}$ and $\mathbf{n} = \mathbf{u} \sin \frac{\Theta}{2}$. In the case specified by (1a), Θ is the amount that the modeled body must be rotated about \mathbf{u} to reach the attitude of \mathcal{B} starting from \mathcal{I} . Accordingly, the instantaneous AEQ is given by $\mathbf{q}_e = \mathbf{q}^{-1} \otimes \mathbf{q}_d = [m_e \ \mathbf{n}_e^T]^T$, with $m_e = \cos \frac{\Theta_e}{2}$ and $\mathbf{n}_e = \mathbf{u}_e \sin \frac{\Theta_e}{2}$, where Θ_e is the amount that \mathcal{B} must be rotated about the attitude-error Euler axis, \mathbf{u}_e , to reach the orientation of the desired body-fixed frame, \mathcal{B}_d ; and, \mathbf{q}_d is a unit quaternion that represents the attitude of \mathcal{B}_d relative to \mathcal{I} . In practice, \mathbf{q}_d is either defined by a user, as described in Section IV, or generated by a position-control scheme, as explained in [4]. For the purpose of real-time implementation, the control algorithm must compute the desired angular-velocity quaternion of the rotational system, written in \mathcal{B}_d coordinates, according to

$$\begin{bmatrix} 0 \\ \dot{\boldsymbol{\omega}}_d \end{bmatrix} = 2\mathbf{q}_d^{-1} \otimes \dot{\mathbf{q}}_d. \quad (2)$$

Next, to obtain the desired angular velocity of the robot in \mathcal{B} coordinates, we use the transformation $\boldsymbol{\omega}_d = \mathbf{S}^T \mathbf{S}_d \dot{\boldsymbol{\omega}}_d$, where \mathbf{S}_d transforms vectors from \mathcal{B}_d to \mathcal{I} coordinates and \mathbf{S}^T transforms vectors from \mathcal{I} to \mathcal{B} coordinates. Then, the control law computes the torque input according to

$$\boldsymbol{\tau}_b = \mathbf{J} (k_q \mathbf{n}_e + k_\omega \boldsymbol{\omega}_e + \dot{\boldsymbol{\omega}}_d) + \boldsymbol{\omega} \times \mathbf{J} \boldsymbol{\omega}, \quad (3)$$

where k_q and k_ω are scalar positive controller gains; $\boldsymbol{\omega}_e = \boldsymbol{\omega}_d - \boldsymbol{\omega}$ is the angular-velocity tracking error; $\mathbf{J} \dot{\boldsymbol{\omega}}_d$ is a feedforward term that cancels the left-hand side of (1b) and is included aiming to provide faster tracking performance; and, $\boldsymbol{\omega} \times \mathbf{J} \boldsymbol{\omega}$ is a feedback-linearization term that cancels the nonlinearity present in (1b).

As discussed in [4], the CL rotational dynamics obtained by substituting the *right-hand side* (RHS) of (3) into (1b) exhibit two equilibria corresponding to the same kinematic condition but with different stability properties—one asymptotically stable and another unstable. It is straightforward to see that, at both fixed points, $\mathbf{n}_e = \mathbf{0}$. Therefore, if the state of the CL system were to be exactly at the unstable equilibrium point, the control torque specified by (3) would not compel the controlled rotational system to execute a 2π -rad rotation and converge to the stable equilibrium point, thus preventing global asymptotic stability in $SO(3)$. However, in any real-life application, any deviation from the unstable fixed point would make $\mathbf{n}_e \neq \mathbf{0}$ and, therefore, for all practical purposes, we can confidently assume that the torque generated according to (3) forces the CL system's state to converge to the stable equilibrium point. Furthermore, since \mathbf{n}_e is scaled by the factor $\sin \frac{\Theta_e}{2}$,

the first term in (3) does not provide the maximum allowable control effort when the controlled rotational system is at the farthest orientation from the stable CL equilibrium AEQ. In fact, this term reaches its minimum value at the unstable CL equilibrium AEQ, where $\sin(2\pi/2) = 0$; its maximum at $\sin(\pi/2) = 1$; and, its minimum again at the stable CL equilibrium AEQ, where $\sin(0/2) = 0$. These observations contradict the expected behavior of the proportional action of a feedback controller. We address this issue in the next section by proposing a new generalized axis-angle attitude law for controlling rotational systems in the 3D space.

III. GENERALIZED AXIS-ANGLE ATTITUDE CONTROL

A. A New Class of Control Laws

Let $\gamma : \mathbb{R} \mapsto \mathbb{R}$ be an extended \mathcal{K}_∞ function. Then, for a system whose dynamics evolve on $SO(3)$, the rotational errors to be minimized can be represented as

$$\alpha_e = \gamma(\Theta_e) \mathbf{u}_e \quad \text{and} \quad \omega_e, \quad (4)$$

where α_e is a *scaled Euler axis* (SEA) aligned with \mathbf{u}_e , whose magnitude—measured by any vector norm—scales with the value of Θ_e . Without loss of coverage of $SO(3)$, Θ_e can be restricted to any half-open interval spanning 2π . In addition, given a selected interval, there exists a unique axis-angle pair representing any geometrically nontrivial attitude error; namely, $\Theta_e \neq 2\pi k, \forall k \in \mathbb{Z}$. When the attitude error is trivial, the corresponding rotation axis is not uniquely defined and can take any value in S^2 . Note, however, that α_e is still well defined at $\Theta_e = 0$. For any nontrivial case, the selected domain for Θ_e yields a $\{\mathbf{u}_e, \Theta_e\}$ pair that defines one of two geometrically unique and opposite physical rotations. To deal with this rotational ambiguity, at initial time t_0 , the direction of \mathbf{u}_e is selected to minimize a cost two-valued function over the interval $\Theta_e \in [0, 2\pi)$, as described in [1]. Thus, using the rotational errors specified by (4), we define the proposed generic control law as

$$\tau_\gamma = \mathbf{J} (k_\alpha \alpha_e + k_\delta \dot{\alpha}_e + k_\omega \omega_e + \dot{\omega}_d) + \omega \times \mathbf{J} \omega, \quad (5)$$

in which k_α, k_δ , and $k_\omega \in \mathbb{R}_{>0}$. Then, from simple substitution of (4) into (5), we obtain that

$$\tau_\gamma = \mathbf{J} [k_\alpha \gamma(\Theta_e) \mathbf{u}_e + k_\delta \gamma(\Theta_e) \dot{\mathbf{u}}_e + k_\delta \dot{\gamma}(\Theta_e) \mathbf{u}_e + k_\omega \omega_e + \dot{\omega}_d] + \omega \times \mathbf{J} \omega. \quad (6)$$

B. Closed-Loop Dynamics & Equilibrium Points

It is straightforward to see that for the control input defined by (6), the CL rotational-error dynamics can be written as

$$\dot{\mathbf{q}}_e = \frac{1}{2} \begin{bmatrix} 0 \\ \omega_e \end{bmatrix} \otimes \mathbf{q}_e, \quad (7a)$$

$$\dot{\omega}_e = -k_\alpha \gamma(\Theta_e) \mathbf{u}_e - k_\delta \left[\gamma(\Theta_e) \dot{\mathbf{u}}_e + \frac{\partial \gamma}{\partial \Theta_e} (\mathbf{u}_e^T \omega_e) \mathbf{u}_e \right] - k_\omega \omega_e. \quad (7b)$$

Also, it can be shown that $\dot{\Theta}_e = \mathbf{u}_e^T \omega_e$. Next, to find the equilibrium point(s) of the system specified by (7a)–(7b), we

solve for

$$-\frac{1}{2} \mathbf{n}_e^T \omega_e = 0, \quad (8a)$$

$$-\frac{1}{2} (\mathbf{n}_e \times \omega_e - m_e \omega_e) = \mathbf{0}_{3 \times 1}, \quad (8b)$$

$$-k_\alpha \gamma(\Theta_e) \mathbf{u}_e - k_\delta \gamma(\Theta_e) \dot{\mathbf{u}}_e - k_\omega \omega_e = \mathbf{0}_{3 \times 1}. \quad (8c)$$

For (8b) to be satisfied, both terms inside the parenthesis must be zero because they are orthogonal. For both these terms to be zero, one of the following propositions must hold: (i) $\mathbf{n}_e \parallel \omega_e$ and $m_e = 0$; (ii) $\omega_e = \mathbf{0}$; (iii) $\mathbf{n}_e = \omega_e = \mathbf{0}$. Also, for (8a) to be satisfied, either (ii) or (iii) is true, $\mathbf{n}_e = \mathbf{0}$, or $\mathbf{n}_e \perp \omega_e$. Since \mathbf{n}_e and ω_e cannot simultaneously be orthogonal and parallel, the only viable option is either (ii) or (iii). The fulfillment of either (ii) or (iii) requires that the solution to (8a)–(8c) satisfies $\omega_e^* = \mathbf{0}$. Since \mathbf{u}_e is a unit vector evolving on S^2 , it follows that $\mathbf{u}_e \perp \dot{\mathbf{u}}_e$ and, therefore, for (8c) to be satisfied, $\gamma(\Theta_e) = 0$. Last, recalling that $\gamma(\Theta_e)$ is an extended \mathcal{K}_∞ function and, therefore, $\gamma(0) = 0$, we conclude that $\Theta_e^* = 0$.

It is important to note that for the law specified by (6), we selected $\gamma(\Theta_e)$ to be an extended \mathcal{K}_∞ function in order to enforce the existence of a unique zero for $\gamma(\Theta_e)$ and a unique equilibrium point for the CL dynamics given by (7a)–(7b), over the selected range of Θ_e . In summary, the CL dynamics resulting from using the control input specified by (6) exhibit a unique equilibrium point, given by the quaternion-vector pair $\mathbf{q}_e^* = [1 \ 0 \ 0 \ 0]^T$ and $\omega_e^* = \mathbf{0}$. This result does not contradict the topological obstruction discussed in [17] and references therein, according to which every continuous time-invariant CL vector field on $SO(3)$ must exhibit more than one equilibrium point because, for the selected function $\gamma(\cdot)$ and range for Θ_e , the term $\gamma(\Theta_e) \mathbf{u}_e$ is discontinuous at $\Theta_e = 2\pi$ rad. As a consequence, the resulting CL dynamics specified by (7a)–(7b) are also discontinuous, which forces the existence of a unique fixed point, similarly to the cases presented in [8] and references therein. Because of the imposed discontinuity on the CL dynamics, to analyze the system of differential equations given by (7a)–(7b), we use Carathéodory's concept of solution as stated in Definition 2.1 of [20].

C. Stability Analysis

Theorem 1. *Let the attitude and angular-velocity references, \mathbf{q}_d and ω_d , be smooth and bounded functions of time. Also, let the real controller gains satisfy $k_\delta, k_\omega > 0$, and $k_\alpha > \frac{k_\delta k_\omega}{4}$. Then, the fixed point $\{\Theta_e^*, \omega_e^*\}$ of the CL state-space rotational dynamics specified by (7a) and (7b) is globally asymptotically stable.*

Proof. Let a candidate Lyapunov function be given by

$$V = [\gamma(\Theta_e) \mathbf{u}_e^T \quad \omega_e^T] \begin{bmatrix} \frac{k_\delta^2}{2k_\alpha} & \frac{k_\delta}{2k_\alpha} \\ \frac{2k_\alpha}{k_\delta} & 1 \end{bmatrix} \begin{bmatrix} \gamma(\Theta_e) \mathbf{u}_e \\ \omega_e \end{bmatrix} + \int_0^{\Theta_e} \gamma(\phi) d\phi. \quad (9)$$

It is straightforward to show that the eigenvalues of the matrix in the quadratic term of (9) are

$$\lambda_1 = 0 \quad \text{and} \quad \lambda_2 = \frac{k_\delta^2 + 1}{2k_\alpha}. \quad (10)$$

Therefore, the quadratic term in (9) is positive semidefinite and V is positive definite because the second term is positive definite as long as $\gamma(\cdot)$ exists strictly in the first and third quadrants, which is true for any extended \mathcal{K}_∞ function. This is a sufficient but not a necessary condition for positive definiteness. To continue, we expand V as

$$V = \frac{k_\delta^2}{2k_\alpha} \gamma^2(\Theta_e) + \frac{k_\delta}{k_\alpha} \gamma(\Theta_e) \mathbf{u}_e^T \omega_e + \frac{1}{2k_\alpha} \omega_e^T \omega_e + \int_0^{\Theta_e} \gamma(\phi) d\phi, \quad (11)$$

and compute its time derivative, which yields

$$\begin{aligned} \dot{V} &= \frac{k_\delta^2}{k_\alpha} \gamma(\Theta_e) \frac{\partial \gamma}{\partial \Theta_e} \dot{\Theta}_e \\ &+ \frac{k_\delta}{k_\alpha} \left[\frac{\partial \gamma}{\partial \Theta_e} \dot{\Theta}_e \mathbf{u}_e^T \omega_e + \gamma(\Theta_e) \dot{\mathbf{u}}_e^T \omega_e + \gamma(\Theta_e) \mathbf{u}_e^T \dot{\omega}_e \right] \\ &+ \frac{1}{k_\alpha} \omega_e^T \dot{\omega}_e + \gamma(\Theta_e) \dot{\Theta}_e, \end{aligned} \quad (12)$$

which can be simplified by recalling that $\dot{\Theta}_e = \mathbf{u}_e^T \omega_e$, noticing that $\dot{\mathbf{u}}_e^T \mathbf{u}_e = 0$ because $\mathbf{u}_e \in \mathcal{S}^2$, and substituting (7b) into (12). Namely,

$$\begin{aligned} \dot{V} &= \frac{k_\delta^2}{k_\alpha} \gamma(\Theta_e) \frac{\partial \gamma}{\partial \Theta_e} \mathbf{u}_e^T \omega_e \\ &+ \frac{k_\delta}{k_\alpha} \left[\frac{\partial \gamma}{\partial \Theta_e} \mathbf{u}_e^T \omega_e \mathbf{u}_e^T \omega_e + \gamma(\Theta_e) \dot{\mathbf{u}}_e^T \omega_e - k_\alpha \gamma^2(\Theta_e) \right. \\ &\quad \left. - k_\delta \gamma(\Theta_e) \frac{\partial \gamma}{\partial \Theta_e} (\mathbf{u}_e^T \omega_e) - k_\omega \gamma(\Theta_e) \mathbf{u}_e^T \omega_e \right] \\ &+ \frac{1}{k_\alpha} \omega_e^T \left[-k_\alpha \gamma(\Theta_e) \mathbf{u}_e - k_\delta \left(\gamma(\Theta_e) \dot{\mathbf{u}}_e \right. \right. \\ &\quad \left. \left. + \frac{\partial \gamma}{\partial \Theta_e} (\mathbf{u}_e^T \omega_e) \mathbf{u}_e \right) - k_\omega \omega_e \right] + \gamma(\Theta_e) \mathbf{u}_e^T \omega_e. \end{aligned} \quad (13)$$

Thus, after canceling out the terms with equal magnitudes and opposite signs, we obtain

$$\begin{aligned} \dot{V} &= -k_\delta \gamma^2(\Theta_e) - \frac{k_\delta k_\omega}{k_\alpha} \gamma(\Theta_e) \mathbf{u}_e^T \omega_e - \frac{k_\omega}{k_\alpha} \omega_e^T \omega_e \\ &= - \begin{bmatrix} \gamma(\Theta_e) \mathbf{u}_e^T & \omega_e^T \end{bmatrix} \mathbf{W} \begin{bmatrix} \gamma(\Theta_e) \mathbf{u}_e \\ \omega_e \end{bmatrix}, \end{aligned} \quad (14)$$

where

$$\mathbf{W} = \begin{bmatrix} k_\delta & \frac{k_\delta k_\omega}{2k_\alpha} \\ \frac{k_\delta k_\omega}{2k_\alpha} & \frac{k_\omega}{k_\alpha} \end{bmatrix}, \quad (15)$$

which can be made positive definite by selecting

$$\{k_\delta, k_\omega\} > 0 \quad \text{and} \quad k_\alpha > \frac{k_\delta k_\omega}{4}, \quad (16)$$

thus also enforcing that $\dot{V}(t) < 0$. Last, by noticing that V , as specified by (9), is radially unbounded, we conclude that the unique fixed point of the CL dynamics given by (7a)–(7b), $\{\Theta_e^*, \omega_e^*\}$, is globally asymptotically stable. \square

A robustness analysis of the proposed control law is outside the scope of this letter; however, this task can be performed using the Lyapunov-based methods presented in [21].

D. Discussion

There exist infinitely many valid choices of $\gamma(\cdot)$ functions; some superior to the rest. For example, a sigmoid function is an extended class \mathcal{K}_∞ function that provides tunable saturation while maintaining linearity near the equilibrium. Namely,

$$\gamma(\Theta_e) = \Theta_{\max} \frac{1 - e^{-\xi \frac{\Theta_e}{\Theta_{\max}}}}{1 + e^{-\xi \frac{\Theta_e}{\Theta_{\max}}}}, \quad (17)$$

where Θ_{\max} and ξ are design parameters. In this context, Θ_{\max} is the angle at which the maximum magnitude of the actuation torque occurs and ξ determines the rate at which the magnitude of $\gamma(\Theta_e)$ changes with respect to Θ_e . Taking the partial derivative of (17) with respect to Θ_e yields

$$\frac{\partial \gamma}{\partial \Theta_e} = \frac{2\xi e^{-\xi \frac{\Theta_e}{\Theta_{\max}}}}{\left(1 + e^{-\xi \frac{\Theta_e}{\Theta_{\max}}}\right)^2}, \quad (18)$$

which provides insights and can be used to guide the process of controller synthesis. In particular, the slope at the origin has the form $\frac{\partial \gamma}{\partial \Theta_e}(0) = \frac{\xi}{2}$, in which ξ can be tuned taking into consideration, for example, actuator limitations and control objectives.

IV. SIMULATION AND EXPERIMENTAL RESULTS

A. Numerical Simulations

To systematically assess the functionality and performance of the proposed generalized control law, we compared a controller synthesized using this new approach with two benchmark schemes through numerical simulations. The first scheme used for comparison uses the quaternion-based attitude control law specified by (3), τ_b ; the second is the high-performance geometric method presented in [12], whose corresponding attitude control law here we denote by τ_g . We implemented and ran the simulations in Simulink 25.2 (MATLAB R2025b) using the Dormand-Prince algorithm with a fixed step of 10^{-4} s. The open-loop dynamical model specified by (1a)–(1b) was incorporated into the simulations with the parameters of

the Crazyflie 2.1 platform—shown in Fig. 1—and empirically selected controller gains that satisfy the stability conditions for the three compared control laws. Specifically, we selected $\mathbf{J} = \text{diag}\{16.6, 16.7, 29.3\} \cdot 10^{-6} \text{ kg} \cdot \text{m}^2$, $k_q = 10^3 \text{ N} \cdot \text{m}$, and $k_\omega = 10^2 \text{ N} \cdot \text{m} \cdot \text{s}$ for τ_b specified by (3). For τ_γ specified by (5), we selected $k_\alpha = 10^3 \text{ N} \cdot \text{m}$, $k_\omega = 10^2 \text{ N} \cdot \text{m} \cdot \text{s}$, and $k_\delta = 10 \text{ N} \cdot \text{m} \cdot \text{s}$ with $\gamma(\Theta_e)$ defined by (17). For $\gamma(\Theta_e)$, we used $\Theta_{\max} = 1 \text{ rad}$ and $\xi = 1.5$, which were chosen considering the actuator characteristics of the experimental platform. The controller gains for τ_g were specified aiming to ensure an objective comparison. For consistency with previous published results, we implemented both τ_γ and τ_b in combination with the *model predictive selection* (MPS) algorithm presented in [1], according to which the initial direction of \mathbf{u}_e , encoded by $\sigma \in \{-1, +1\}$, minimizes

$$\Gamma(\sigma, t) = \int_t^{t+t_h} [\tau^T(\sigma, \zeta) \mathbf{R} \tau(\sigma, \zeta) + \mathbf{n}_e^T(\zeta) \mathbf{Q} \mathbf{n}_e(\zeta)] d\zeta, \quad (19)$$

where $t_h = 0.2 \text{ s}$; $\mathbf{R} = \mathbf{I}$; and, $\mathbf{Q} = 10^{-6} \cdot \mathbf{I}$. In the simulations, $\tau \in \{\tilde{\tau}_b(\sigma), \tilde{\tau}_\gamma(\sigma)\}$, with $\tilde{\tau}_b(\sigma)$ defined as in [1] and

$$\tilde{\tau}_\gamma(\sigma) = \mathbf{J} [k_\alpha \alpha_e(\sigma) + k_\delta \dot{\alpha}_e(\sigma) + k_\omega \omega_e + \dot{\omega}_d] + \omega \times \mathbf{J} \omega, \quad (20)$$

in which $\alpha_e(\sigma) = \sigma \gamma(\Phi_e) \mathbf{u}_e$ and $\Phi_e = (1 - \sigma) \pi + \sigma \Theta_e$. Note that for $\sigma = +1$, $\Phi_e = \Theta_e$, and for $\sigma = -1$, $\Phi_e = 2\pi - \Theta_e$.

In total, we performed 10908 simulations of high-speed tumble-recovery maneuvers, in which the control objective was to stabilize the orientation of the UAV from an initial state with arbitrary attitude and angular velocity. Consistent with stabilization, for each simulation, the desired state was set to $\mathbf{q}_d = [1 \ 0 \ 0 \ 0]^T$ and $\omega_d = \mathbf{0} \text{ rad} \cdot \text{s}^{-1}$. The directions of the initial Euler axes of rotation, $\mathbf{u}_0 = \mathbf{u}(t_0)$, were randomly selected from the unit sphere using a uniform distribution, and the initial rotations about \mathbf{u}_0 , $\Theta_0 = \Theta(t_0)$, were taken from the set $[1 : 180]^\circ$ in steps of 5° . For each Θ_0 , we varied the initial angular velocity, ω_0 , from $-30 \cdot \mathbf{u}_0$ to $30 \cdot \mathbf{u}_0 \text{ rad} \cdot \text{s}^{-1}$ with the magnitude incremented in steps of $0.6 \text{ rad} \cdot \text{s}^{-1}$. For each simulation corresponding to a Θ_0 value, we computed the mean and *standard deviation* (SD) of the stabilization time, t_s —defined as the time it takes for Θ_e to reach a value lower than 15° —across the 101 different values of ω_0 . Fig. 2(a) shows how the mean (solid line) and SD (reduced-opacity band) of the stabilization time vary as functions of the initial rotation error, $\Theta_{e,0}$, for the three simulated controllers. As seen, the means of the stabilization time obtained with the three controllers are similar for small values of $\Theta_{e,0}$; however, for larger values of $\Theta_{e,0}$ the means of the stabilization time obtained with τ_γ are notably smaller, even though τ_g produces a better performance in some cases—as evidenced by the SD data. Fig. 2(b) shows the mean and SD of the control effort—defined as $\Lambda = \int_0^1 \|\tau(t)\|_2 dt$, with $\tau \in \{\tilde{\tau}_b, \tau_g, \tilde{\tau}_\gamma\}$ —as functions of $\Theta_{e,0}$, for the same simulations corresponding to Fig. 2(a). Although the means of the control effort obtained with the three controllers are similar for small values of $\Theta_{e,0}$, the values of Λ corresponding to τ_b and τ_γ decrease as $\Theta_{e,0}$ increases. Remarkably, the proposed controller consistently requires less control effort while achieving a lower mean stabilization time compared to the two benchmark controllers.

Fig. 2(c) shows the time evolution of Θ_e corresponding to the three simulated control laws, with an initial condition of

Fig. 3. **Experimental setup used during the flight tests.** The attitude flight control experiments were run outdoors using a ground computer equipped with the Crazyradio 2.0 to communicate with the Crazyflie 2.1.

$\Theta_0 = 136^\circ$ and $\omega_0 = 30 \cdot \mathbf{u}_0 \text{ rad} \cdot \text{s}^{-1}$. This initial state corresponds to a kinematic condition in which the direction of the system's initial angular velocity is opposite to that of the shorter rotational path required to eliminate the attitude error. As seen, the controller based on $\tilde{\tau}_\gamma$ achieves a stabilization time of 0.45 s whereas the benchmark controllers—with laws $\tilde{\tau}_b$ and τ_g —achieve stabilization times of 0.58 and 0.49 s , respectively. It is important to note that the initial rotation error for the $\tilde{\tau}_\gamma$ and $\tilde{\tau}_b$ cases is 224° , which means that these two laws applied the control torque in the direction of the longer rotational path required to eliminate the attitude error. Fig. 2(d) shows the magnitudes of the corresponding SEAs, $\|\mathbf{n}_e\|_2$ and $\|\alpha_e\|_2$. As seen, $\|\mathbf{n}_e\|_2$ increases as the control error decreases down to $\Theta_e = 180^\circ$ and starts decreasing after passing through that point (see inset), which highlights the characteristic behavior of quaternion-based controllers. In contrast, $\|\alpha_e\|_2$ decreases with Θ_e , as intended by design.

B. Real-Time Flight Experiments

To assess and demonstrate the suitability and performance of the proposed axis-angle control approach, we performed real-time flight experiments using the same three controllers described in Section IV-A. As depicted in Fig. 3, the flight tests were conducted outdoors, using a ground computer—equipped with the Crazyradio 2.0 2.4-GHz USB radio transceiver—to send initialization and stop commands, and collect the flight and control data at a rate of 100 Hz . During each test, the UAV was required to execute a high-speed tumble-recovery maneuver after a throw launch. A representative experiment consists of two stages. In the first stage, the tested UAV is thrown into the air with an arbitrary high angular velocity, while the controller and propellers remain inactive; in the second stage, the controller and propellers are activated. Throughout a maneuver, the flier operates entirely autonomously, using only onboard sensing and computation, with the tested attitude controller running at 500 Hz .

Fig. 4(a) presents the time evolution of Θ_e for different experiments with similar initial conditions, using the three tested control laws. As seen, the stabilization times corresponding to $\tilde{\tau}_b$, τ_g , and $\tilde{\tau}_\gamma$ are of 0.57 , 0.50 , and 0.48 s , respectively. Interestingly, the corresponding values of Λ for the τ_g and $\tilde{\tau}_\gamma$ laws are $1.76 \cdot 10^{-4}$ and $4.56 \cdot 10^{-5}$, which indicates that the proposed method achieved a lower stabilization time using only 25% of the control effort measured for the geometric-control case. Fig. 4(b) presents the time evolutions

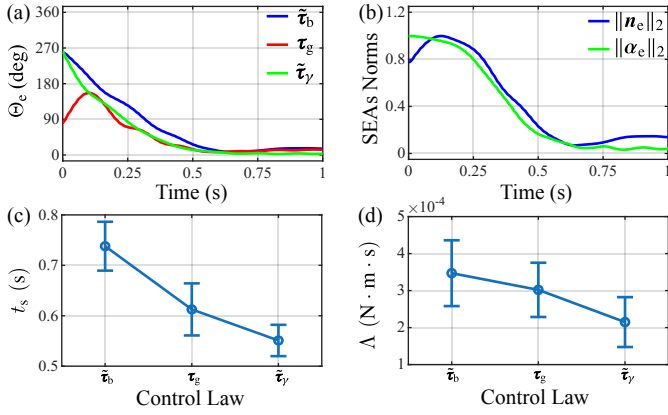

Fig. 4. Experimental results. (a) Rotation errors corresponding to three tests employing τ_b , τ_g , and τ_γ . (b) Magnitudes of the SEAs $\|n_e\|_2$ and $\|\alpha_e\|_2$ corresponding to τ_b and τ_γ , respectively. (c) Comparison of mean (circle) and SEM (vertical bars) of the stabilization times using τ_b , τ_g , and τ_γ over 30 experiments. (d) Comparison of mean and SEM of the control effort using τ_b , τ_g , and τ_γ over 30 experiments.

of the 2-norms of the SEA vectors $\|n_e\|_2$ and $\|\alpha_e\|_2$. Similarly to the simulation cases discussed in Section IV-A, it can be observed that $\|n_e\|_2$ increases as Θ_e decreases down to 180° , and decreases after passing through this point. In contrast, over the entire range of operation, $\|\alpha_e\|_2$ decreases and increases with Θ_e , as intended by design. Experiments of this type can be viewed in the video available as a Supplemental Item.

In Fig. 4(c), each data point indicates the mean and *standard error of the mean* (SEM) of the stabilization times corresponding to 30 back-to-back experiments performed using each of the three control laws compared in this letter. The means of the stabilization times corresponding to τ_b , τ_g , and τ_γ are 0.74, 0.61, and 0.55 s, respectively. In Fig. 4(d), each data point indicates the the mean and SEM of the control effort, Δ , corresponding to the same experiments in Fig. 4(c). Specifically, the means of Δ corresponding to τ_b , τ_g , and τ_γ are $3.47 \cdot 10^{-4}$, $3.02 \cdot 10^{-4}$, and $2.15 \cdot 10^{-4} \text{ N}\cdot\text{m}\cdot\text{s}$, respectively. Although the differences between these values are not substantial, the experimental data provide compelling evidence of the suitability and superior performance of the proposed approach; particularly, under nonideal conditions due to the presence of actuator saturation, model uncertainty, and disturbances. We inferred that these nonideal conditions also explain the discrepancies between the simulated and experimental Δ values. Last, it is important to mention that the large variability in the experimental data is expected due to the random nature of tumble-recovery experiments.

V. CONCLUSION

We introduced a new class of axis-angle attitude control laws that provide substantial design flexibility with guaranteed closed-loop stability while ensuring a greater proportional control effort the farther away the system's state is from the unique stable fixed AEQ of the CL dynamics. This characteristic is particularly useful when the proposed approach is used in combination with intelligent switching schemes. Evidence regarding functionality and high performance was provided in the form of data obtained through simulations and outdoor flight tests, during which we commanded a quadrotor to autonomously execute tumble-recovery maneuvers in the

air. The new method consistently achieved reduced stabilization times and required less control effort compared to the quaternion-based and geometric-control methods used as benchmarks.
