

Identification with Orthogonal Basis Functions: Convergence Speed, Asymptotic Bias, and Rate-Optimal Pole Selection

Jiayun Li¹, Yiwen Lu¹, Yilin Mo¹ and Jie Chen²

Abstract—This paper is concerned with performance analysis and pole selection problem in identifying linear time-invariant (LTI) systems using orthogonal basis functions (OBFs), a system identification approach that consists of solving least-squares problems and selecting poles within the OBFs. Specifically, we analyze the convergence properties and asymptotic bias of the OBF algorithm, and propose a pole selection algorithm that robustly minimizes the worst-case identification bias, with the bias measured under the \mathcal{H}_2 error criterion. Our results include an analytical expression for the convergence rate and an explicit bound on the asymptotic identification bias, which depends on both the true system poles and the preselected model poles. Furthermore, we demonstrate that the pole selection algorithm is asymptotically optimal, achieving the fundamental lower bound on the identification bias. The algorithm explicitly determines the model poles as the so-called Tsuji points, and the asymptotic identification bias decreases exponentially with the number of basis functions, with the rate of decrease governed by the hyperbolic Chebyshev constant. Numerical experiments validate the derived bounds and demonstrate the effectiveness of the proposed pole selection algorithm.

Index Terms—LTI systems, system identification, orthogonal basis functions, least-squares algorithms.

I. INTRODUCTION

System identification has long been a focus in the design of control systems, and more broadly in the modeling of dynamical systems [1], statistical time series analysis [2], and in system realization theory [3], with early inspirations going back to the works of Zadeh [4] and Kalman [5] in the 1960s. Traditional identification methods usually address this problem in the asymptotic sense, where the number of data samples tends to infinity. The central issue is whether the identified mathematical model asymptotically approaches the true physical system, depending on *a priori* information available about the system and *a posteriori* data acquired experimentally, and, if so, whether a bias arises between the model and the system. Classical identification algorithms, such as the Ho-Kalman algorithm [6] and the multivariable output-error state space (MOESP) approach [7], are known to be asymptotically unbiased given infinite samples under certain conditions [1, 8, 9]. However, these algorithms are typically nonlinear (involving nonlinear operations such as SVD or matrix inversion of the Hankel matrices) with respect to the collected data and may exhibit high sensitivity to noise when only finite-length samples are available [10, 11],

resulting in potential high signal-to-noise ratio requirement and thus high sample complexity. This behavior is also illustrated in a numerical example in Fig. 6.

It is intuitively plausible that the availability of *a priori* information could improve the data efficiency of identification algorithms. In this vein, several methods [12–14] seek to approximate a system’s transfer function using a linear combination of orthogonal basis functions (OBFs). A least-squares (LS) algorithm is leveraged to identify the coefficients of OBFs, which is linear with respect to the data. In contrast, the set of the OBFs, parametrized by their poles, are preselected based on *a priori* information, eliminating the need for nonlinear identification algorithms to estimate system poles. Common choices for OBFs include the Laguerre [15] and the Kautz functions [13]. Furthermore, Van den Hof et al. [16] propose the generalized OBF (GOBF) and derive upper bounds on the asymptotic identification bias as sample size approaches infinity [16–18]. Ninness and Gustafsson [19] develop a unifying construction of the OBFs, with which they show that the identification result converges in the mean-square sense at a rate of $O(N^{-1})$ with respect to the sample size N . Additionally, Ninness and Gomez [18] quantify the asymptotic bias in identification using OBF methods, which can vary significantly depending on the choice of OBFs. Consequently, the selection of poles in the OBFs plays a crucial role in the quality of the identified model, directly influencing the bias of the identification algorithm.

To facilitate the selection of OBF poles, one line of work aims to address this difficulty from a *robustness* perspective, ensuring any system consistent with the given *a priori* information can be accurately approximated by the OBFs with the selected poles. For example, Oliveira e Silva [20, Chapter 11] introduces a pole selection algorithm for the OBFs by numerically solving a nonlinear minimax optimization problem, based on the pole region of the true system, i.e., a closed set in the complex plane that encompasses all poles of the true system, as specified by *a priori* information. However, this problem involves a non-convex semi-infinite programming, which may suffer from drastic growth in computational complexity with the number of poles [20, Chapter 11]. Toth et al. [21] propose a clustering algorithm for selecting OBF poles in the context of linear parameter-varying systems. However, the algorithm requires an ensemble of sampled system poles, a requirement that renders the algorithm’s performance heavily dependent on the accuracy of the sampled poles.

There are also less conventional methods that seek to

select the OBF poles adaptively, such as particle swarm optimization [22] and genetic optimization [23]. Other approaches include solving an empirical Bayes problem [24–26] and applying a greedy algorithm using frequency-domain data [27, 28]. However, these methods often suffer from high computational complexity and may become trapped in local optima.

This paper enhances the OBF approach by proposing an optimal pole selection algorithm to *robustly* minimize the worst-case identification bias among a particular class of systems. To this end, we first analyze the convergence properties and the asymptotic bias of OBF algorithms (i.e., with prescribed poles and OBF bases). We then solve an asymptotic pole selection problem. We show that the so-called Tsuji points [29] asymptotically achieve the minimal identification bias possible and hence are asymptotically optimal poles. These points can be determined by solving a maximization problem on the boundary of the pole region, ridding of the need to solve a significantly more complex minimax problem, such as the one proposed by Oliveira e Silva [20, Chapter 11]. We also present an algorithm to compute a set of near-optimal initial points for the maximization problem, thus alleviating the issue of local optimality. The resulting system identification bias asymptotically achieves the fundamental lower bound on the worst-case identification bias. Our main contributions can be summarized as follows:

- 1) With preselected bases and corresponding poles, we show that the identification error of the OBF methods measured under the \mathcal{H}_2 norm converges to an asymptotic bias almost surely at a rate of $O(N^{-0.5+\epsilon})$, for any $\epsilon > 0$. We also derive an upper bound on the identification bias, which depends on the discrepancy between the true system poles and the preselected poles in the OBF basis functions. When system poles are known to lie within a specific region \mathcal{D} within the unit disk in the complex plane, we establish a fundamental lower bound on the asymptotic bias, showing that the worst case bias decreases at a rate of at most $O(\tau(\mathcal{D})^q)$, where $\tau(\mathcal{D}) < 1$ is the hyperbolic Chebyshev constant of \mathcal{D} and q denotes the number of bases.
- 2) The search for optimal poles, which minimize the asymptotic bias against all possible systems consistent with the *a priori* information, naturally leads to a minimax problem. We propose to replace this minimax problem with a maximization problem on the boundary of the pole region, where the optimal solutions are the Tsuji points. More specifically, we show that the Tsuji points asymptotically achieve the fundamental lower bound on the worst-case identification bias as the number of bases tends to infinity.
- 3) By a further analysis, the fundamental lower bound on the identification bias indicates that the number of data length required for identification of n -dimensional systems, known as the sample complexity, grows asymptotically at a rate of $O(\tau(\mathcal{D})^{-n})$. This points to

the intrinsic difficulty in identifying a system when its poles are unknown, especially for high-order systems.

Paper structure: In Section II, we introduce relevant concepts and results in complex analysis. Section III formulates the system identification problem and briefly reviews the OBF method. Following this, Section IV analyzes the performance of the OBF method, establishing an almost sure convergence rate with respect to the sample size and deriving an upper bound for the asymptotic identification bias. Section V derives a fundamental lower bound on the worst-case asymptotic bias and proposes the Tsuji pole selection algorithm, along with an analysis of its performance. In Section VI, a fundamental limit on the sample complexity of identifying the system poles is derived. Section VII provides numerical results to demonstrate the efficacy of the algorithm. Section VIII concludes the paper.

Notations: The symbol \mathbf{I}_n denotes the n -dimensional unit matrix, and $\mathbf{1}_n$ is an n -dimensional column vector with entries all equal to 1. Similarly, $\mathbf{0}_n$ denotes the n -dimensional zero vector. A^\top denotes the matrix transpose and A^H the conjugate transpose of A . $\|A\|$ denotes the 2-norm for a vector A and Frobenius norm for a matrix A . For a vector \mathbf{x} , $\text{diag}(\mathbf{x})$ denotes the diagonal square matrix with elements of \mathbf{x} on its main diagonal. Moreover, \mathbb{D} denotes the open unit disk on the complex plane, i.e., $\mathbb{D} \triangleq \{z \in \mathbb{C} : |z| < 1\}$. We say that $|f(k)| \sim O(g(k))$ for $g(k) > 0$ if there exists a constant $M > 0$, such that $\lim_{k \rightarrow \infty} |f(k)|/g(k) \leq M$ for all $k = 1, 2, \dots$. The extended expectation \mathbb{E} is defined as $\mathbb{E}(\phi(t)) = \lim_{t \rightarrow \infty} \mathbb{E}(\phi(t))$ for a proper ϕ .

II. MATHEMATICAL PRELIMINARY

In this section, we introduce some concepts and results in *complex analysis*, which will be used in the sequel.

We begin with the *pseudohyperbolic metric*, a classical distance notion in complex analysis (see, e.g., [30]), defined as

$$[z, \mu]_h \triangleq \left| \frac{z - \mu}{1 - \bar{\mu}z} \right| \quad (1)$$

for any z, μ inside the open unit disk. Next, we introduce the notion of *hyperbolic Chebyshev constant* of a closed region \mathcal{D} inside the open unit disk \mathbb{D} .

Definition 1 ((Finite) Hyperbolic Chebyshev constant (following equation (55) in [30]), hyperbolic Chebyshev points). *Let q be an integer and \mathcal{D} a closed subset of the open unit disk \mathbb{D} . The finite hyperbolic Chebyshev constant of \mathcal{D} is defined as*

$$\tau_q(\mathcal{D}) \triangleq \min_{\mu_1, \dots, \mu_q \in \mathcal{D}} \max_{z \in \mathcal{D}} \left(\prod_{k=1}^q [z, \mu_k]_h \right)^{1/q}, \quad (2)$$

and the points $\mu_1, \mu_2, \dots, \mu_q$ that achieve the minimum are called the hyperbolic Chebyshev points of \mathcal{D} . The limit

$$\tau(\mathcal{D}) \triangleq \lim_{q \rightarrow \infty} \min_{\mu_1, \dots, \mu_q \in \mathcal{D}} \max_{z \in \mathcal{D}} \left(\prod_{k=1}^q [z, \mu_k]_h \right)^{1/q}, \quad (3)$$

which always exists, is referred to as the the hyperbolic Chebyshev constant of the region \mathcal{D} .

Similarly, we may define the hyperbolic transfinite diameter and the Tsuji points of a region \mathcal{D} .

Definition 2 (Hyperbolic transfinite diameter, Tsuji points (following equation (54) in [30])). *Let q be an integer and \mathcal{D} a closed subset of the open unit disk \mathbb{D} . Define*

$$d_q(\mathcal{D}) := \max_{z_1, \dots, z_q \in \mathcal{D}} \left\{ \prod_{1 \leq j < k \leq q} [z_j, z_k]_h \right\}^{1/\binom{q}{2}} \quad (4)$$

Here $\binom{q}{2} = q(q-1)/2$ denotes the number of distinct pairs among the q points. The points $z_k, k = 1, \dots, q$ that attain the maximum are called the q -th Tsuji points of \mathcal{D} .

Moreover, the following limit exists and is referred to as the hyperbolic transfinite diameter of \mathcal{D} :

$$d(\mathcal{D}) := \lim_{q \rightarrow \infty} \max_{z_1, \dots, z_q \in \mathcal{D}} \left\{ \prod_{1 \leq j < k \leq q} [z_j, z_k]_h \right\}^{1/\binom{q}{2}}. \quad (5)$$

The hyperbolic Chebyshev constant and the hyperbolic transfinite diameter are known to coincide:

Proposition 3 (see page 278 in [30]). *For any closed set $\mathcal{D} \subset \mathbb{D}$,*

$$\tau(\mathcal{D}) = d(\mathcal{D}). \quad (6)$$

Let $\bar{\mathbb{D}}_\rho$ denote the closed disk with radius $\rho < 1$, i.e., $\bar{\mathbb{D}}_\rho \triangleq \{z : |z| \leq \rho\}$. If $\mathcal{D} \subset \bar{\mathbb{D}}_\rho$, then

$$\tau(\mathcal{D}) = d(\mathcal{D}) \leq \rho. \quad (7)$$

For certain special sets \mathcal{D} , their hyperbolic Chebyshev constants can be found analytically. We summarize some of these results in the following lemma, whose proofs are relegated to Appendix I.

Lemma 4 (Hyperbolic Chebyshev constant of disks and intervals). *Below are some special sets \mathcal{D} whose hyperbolic Chebyshev constants can be computed analytically:*

- 1) *The hyperbolic Chebyshev constant of a disk $\bar{\mathbb{D}}_\rho$ is*

$$\tau(\bar{\mathbb{D}}_\rho) = \rho.$$

- 2) *The hyperbolic Chebyshev constant of a real interval $[\rho_1, \rho_2]$, $-1 < \rho_1 < \rho_2 < 1$ is*

$$\tau([\rho_1, \rho_2]) = \exp \left\{ -\frac{\pi}{2} \frac{K(\sqrt{1-\tilde{\rho}^2})}{K(\tilde{\rho})} \right\},$$

where

$$\tilde{\rho} = \frac{\rho_2 - \rho_1}{1 - \rho_1 \rho_2}, K(\rho) \triangleq \int_0^1 \frac{dx}{\sqrt{(1-x^2)(1-\rho^2 x^2)}}.$$

III. PROBLEM FORMULATION

Consider a stable LTI system with m inputs and p outputs:

$$y_t = G(z)u_t + H(z)e_t = G(z)u_t + v_t, \quad (8)$$

where $\{u_t\}$ is a quasistationary signal and $\{e_t\}$ is an i.i.d. stochastic vector process with zero mean and unit covariance. The variable z represents the time-shift operator, i.e., $zu_t = u_{t+1}$. We make the following assumptions about the system:

Assumption 1.

- 1) *$G(z)$ and $H(z)$ are both strictly stable transfer functions; that is, all the poles of $G(z)$ and $H(z)$ are in \mathbb{D} . Additionally, $G(z)$ has relative degree at least 1.*
- 2) *The system (8) is controlled by a linear controller and is closed-loop stable. The controller can be modeled as another LTI system:*

$$u_t = G_u(z)y_t + H_u(z)\epsilon_t, \quad (9)$$

where $\{\epsilon_t\}$ is an i.i.d. stochastic vector process with zero mean and unit covariance, serving as probing noise and is assumed to be mutually independent with $\{e_t\}$. The controller transfer functions $G_u(z)$ and $H_u(z)$, as well as the realization of the probing signal ϵ_t , are known and available.

Assumption 2 (Persistent excitation). *The externally injected probing component $H_u(z)\epsilon_t$ is persistently exciting of sufficiently high order.*

Assumption 1 and 2 implies that the resulting control input u_t is persistently exciting of sufficiently high order.

Remark 1. Under Assumptions 1 and 2, the plant transfer function $G(z)$ is uniquely identifiable from closed-loop data. The noise model $H(z)$ is not explicitly identified in this work, and its uniqueness is not relevant to the subsequent analysis.

In this paper, we focus on applying the OBF method to identify the system (8). Specifically, we need to approximate $G(z)$ with $\check{G}(z)$, which is a linear combination of a set of predefined basis functions $V_k(z)$:

$$\check{G}(z) = \sum_{k=1}^q \check{R}_k V_k(z). \quad (10)$$

The coefficient matrices in the linear combinations are, in general, complex-valued matrices and satisfy $\check{R}_k \in \mathbb{C}^{p \times m}$. On the other hand, the preselected basis functions $V_k(z)$, characterized by a group of q poles $\{\mu_1, \dots, \mu_q\}$, can be chosen as:

$$V_k(z) = \frac{1}{z - \mu_k}, k = 1, \dots, q, \quad (11)$$

where μ_k are distinct from each other. These bases can be further orthonormalized using standard procedures, to obtain the unified construction of OBFs [19] as follows:

$$\mathcal{V}_k(z) = \frac{\sqrt{1 - |\mu_k|^2}}{z - \mu_k} \prod_{l=1}^{k-1} \frac{1 - \bar{\mu}_l z}{z - \mu_l}, k = 1, \dots, q. \quad (12)$$

This unified construction includes a wide variety of commonly used OBFs, such as Laguerre bases, Kautz bases, and generalized OBF [16]. The readers can refer to [20] for more details.

Remark 2. *Although the orthonormalization procedure may help with the numerical stability of the least-squares algorithm, it does not alter the span of the basis functions, the identification error of the least-squares problem, or the asymptotic approximation bias of the identification discussed later.*

Owing to the equivalence of the span between V_k in (11) and the unified construction \mathcal{V}_k in (12), in the rest of the paper, we slightly abuse the definition by adopting the bases V_k as the preselected bases in the OBF method for simplicity. Then, the OBF identification problem can be stated as follows:

Problem 1 (System identification using preselected V_k).

$$\min_{\tilde{R}_1, \dots, \tilde{R}_q} \left\| G(z) - \sum_{k=1}^q \frac{\tilde{R}_k}{z - \mu_k} \right\|_2. \quad (13)$$

To find a near-optimal solution for Problem 1 in a data-driven manner given N sample pairs $u_{1:N} = \{u_1, \dots, u_N\}$, $y_{1:N} = \{y_1, \dots, y_N\}$, we solve the following least-squares regression [20, Chapter 4]. Under Assumption 2, the resulting control input u_t is persistently exciting of sufficiently high order, which guarantees that the least-squares problem (14) is well-defined after a finite warm-up period:

$$\begin{aligned} & \tilde{R}_1(N), \dots, \tilde{R}_q(N) \\ &= \arg \min_{\tilde{R}_1, \dots, \tilde{R}_q} \frac{1}{N} \sum_{t=1}^N \left\| y_t - \sum_{k=1}^q \frac{\tilde{R}_k}{z - \mu_k} u_t \right\|^2, \end{aligned} \quad (14)$$

where $\|\cdot\|$ denotes the 2-norm of a vector. Then, the identified model using N samples is given by

$$\check{G}_N(z) = \sum_{k=1}^q \frac{\tilde{R}_k(N)}{z - \mu_k}.$$

IV. CONVERGENCE AND ASYMPTOTIC BIAS

The overarching goal of this section is to analyze the convergence property of the least-squares algorithm in solving (14) in the almost sure sense as the number of samples tends to infinity, and to quantify the asymptotic bias using the bases $1/(z - \mu_k)$.

A. Convergence Analysis

Define the solution to the following expected least-squares problem as:

$$(\tilde{R}_1^*, \dots, \tilde{R}_q^*) = \arg \min_{\tilde{R}_1, \dots, \tilde{R}_q} \mathbb{E} \left\| y_t - \sum_{k=1}^q \frac{\tilde{R}_k}{z - \mu_k} u_t \right\|^2, \quad (15)$$

where for a vector (or matrix) valued random process $\{X_t\}$, we denote its limit expected value as $\mathbb{E}(X_t) =$

$\lim_{t \rightarrow \infty} \mathbb{E}(X_t)$ [16]. The corresponding transfer function is given as:

$$\check{G}^*(z) = \sum_{k=1}^q \frac{\tilde{R}_k^*}{z - \mu_k}. \quad (16)$$

The following theorem establishes the property that the identified system $\check{G}_N(z)$ by solving the least-squares problem (14) with N samples converges to $\check{G}^*(z)$ almost surely.

Theorem 5 (Almost sure convergence). *The \mathcal{H}_2 norm of the error between the identified model $\check{G}_N(z)$ using N samples and the asymptotic model $\check{G}^*(z)$ satisfies*

$$\lim_{N \rightarrow \infty} \frac{\|\check{G}_N(z) - \check{G}^*(z)\|_2}{N^{-0.5+\epsilon}} = 0 \text{ a.s.}, \quad (17)$$

for all $\epsilon > 0$.

Proof. Let a state-space realization of the system in (8) be given by [20, Chapter 2]:

$$x_{t+1} = Ax_t + Bu_t + Be_{t+1}, \quad y_t = Cx_t, \quad (18)$$

and let a state-space realization of the input dynamics (9) be

$$\varphi_t = A_\varphi \varphi_{t-1} + B_\varphi y_t + B_\varphi \epsilon_t, \quad u_t = C_\varphi \varphi_t. \quad (19)$$

Then, the overall system incorporating the true system $G(z)$, the input dynamics, and the identified model can be collectively represented by the augmented system

$$\tilde{x}_{t+1} = \tilde{A}\tilde{x}_t + \tilde{w}_t, \quad \psi_t = \tilde{C}\tilde{x}_t, \quad (20)$$

where $\tilde{x}_t = [x_t^\top \ y_t^\top \ \varphi_t^\top \ u_t^\top \ \tilde{x}_t^\top]^\top$, $\psi_t = [y_t^\top \ \tilde{x}_t^\top]^\top$,

$$\tilde{A} = \begin{bmatrix} A & 0 & 0 & B & 0 \\ CA & 0 & 0 & CB & 0 \\ 0 & B_\varphi y & A_\varphi & 0 & 0 \\ 0 & C_\varphi B_\varphi y & C_\varphi A_\varphi & 0 & 0 \\ 0 & 0 & 0 & (\mathbf{1}_q \otimes I_p) & \tilde{A} \end{bmatrix},$$

\tilde{x}_t is defined recursively as:

$$\tilde{x}_{t+1} = \tilde{A}\tilde{x}_t + (\mathbf{1}_q \otimes u_t), \quad t = 1, \dots, N,$$

with $\tilde{x}_0 = 0$, where $\tilde{A} = \text{diag}(\mu_1, \dots, \mu_q) \otimes I_m$, and

$$\tilde{w}_t = \begin{bmatrix} B_e & 0 \\ CB_e & 0 \\ 0 & B_{\varphi\epsilon} \\ 0 & C_{\varphi} B_{\varphi\epsilon} \\ 0 & 0 \end{bmatrix} \begin{bmatrix} e_{t+1} \\ \epsilon_t \end{bmatrix}, \quad \tilde{C} = \begin{bmatrix} 0 & I & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & I \end{bmatrix}.$$

It is easy to verify that \tilde{w}_t is an i.i.d. random noise with zero mean.

Let $\tilde{W} = \lim_{t \rightarrow \infty} \mathbb{E}(\psi_t \psi_t^H)$. We can verify that the augmented system satisfies the assumptions in Lemma 7 of [31], which allows us to prove that for all $\epsilon > 0$,

$$\lim_{N \rightarrow \infty} \frac{\frac{1}{N} \sum_{t=1}^N \psi_t \psi_t^H - \tilde{W}}{N^{-0.5+\epsilon}} = 0 \text{ a.s.}$$

This lemma yields an almost-sure convergence rate of order $N^{-1/2+\epsilon}$ for the *sample covariance* of outputs of stable LTI systems. In the temporally correlated setting considered here,

this martingale-based result plays a role analogous to that of the law of the iterated logarithm in the i.i.d. case.

Moreover, note that the solution to the least-squares problem (14), $\check{R}_k(N)$, is directly related to the subblocks of $\frac{1}{N} \sum_{t=1}^N \psi_t \psi_t^H$, provided that N is sufficiently large to ensure that the solution

$$[\check{R}_1(N) \cdots \check{R}_q(N)] = \left(\frac{1}{N} \sum_{t=1}^N y_t \check{x}_t^H \right) \left(\frac{1}{N} \sum_{t=1}^N \check{x}_t \check{x}_t^H \right)^{-1},$$

exists. Meanwhile, the asymptotic solution \check{R}_k^* exhibits the same relationship with the subblocks of $\check{\mathcal{W}}$. To explicitly express this relationship, we define the matrix function $\mathcal{A}(X)$ for a given matrix $X \in \mathbb{C}^{(p+qm) \times (p+qm)}$ as follows:

$$\mathcal{A}(X) \triangleq \begin{bmatrix} I_p & 0 \end{bmatrix} (\check{\mathcal{W}} - X) \begin{bmatrix} 0 \\ I_{qm} \end{bmatrix} \left(\begin{bmatrix} 0 & I_{qm} \end{bmatrix} (\check{\mathcal{W}} - X) \begin{bmatrix} 0 \\ I_{qm} \end{bmatrix} \right)^{-1}. \quad (21)$$

By Assumption 2, $\lim_{t \rightarrow \infty} \mathbb{E}(\check{x}_t \check{x}_t^H)$ is invertible and for sufficiently large N , $\frac{1}{N} \sum_{t=1}^N \check{x}_t \check{x}_t^H$ is invertible. Therefore, the following equation is well-defined and holds:

$$\begin{aligned} [\check{R}_1(N) \cdots \check{R}_q(N)] &= \mathcal{A} \left(\check{\mathcal{W}} - \frac{1}{N} \sum_{t=1}^N \psi_t \psi_t^H \right), \\ [\check{R}_1^* \cdots \check{R}_q^*] &= \mathcal{A}(0). \end{aligned}$$

Taking notice of the fact that $\mathcal{A}(X)$ is differentiable at 0, by Lemma 3.3 of [31], which ensures that the convergence of $\frac{1}{N} \sum_{t=1}^N \psi_t \psi_t^H$ (and its rate) is preserved under the differentiable mapping $\mathcal{A}(\cdot)$, we obtain that for all $\epsilon > 0$,

$$\lim_{N \rightarrow \infty} \frac{\|\check{R}_k(N) - \check{R}_k^*\|}{N^{-0.5+\epsilon}} = 0 \text{ a.s.}, \quad k = 1, 2, \dots, q. \quad (22)$$

Finally, by the definition of the \mathcal{H}_2 norm,

$$\begin{aligned} \|\check{G}_N(z) - \check{G}^*(z)\|_2 &= (\text{tr}[(\check{R}(N) - \check{R}^*) \Xi_{\mu, \mu} (\check{R}(N) - \check{R}^*)^H])^{1/2} \\ &\leq \|\Xi_{\mu, \mu}\|^{1/2} \|\check{R}(N) - \check{R}^*\|, \end{aligned} \quad (23)$$

where $\|\cdot\|$ denotes the Frobenius norm of a matrix, $\check{R}(N) = [\check{R}_1(N) \cdots \check{R}_q(N)]$, $\check{R}^* = [\check{R}_1^* \cdots \check{R}_q^*]$ and

$$\Xi_{\mu, \mu} = \begin{bmatrix} \frac{1}{1-\mu_1 \bar{\mu}_1} & \frac{1}{1-\mu_1 \bar{\mu}_2} & \cdots & \frac{1}{1-\mu_1 \bar{\mu}_q} \\ \frac{1}{1-\mu_2 \bar{\mu}_1} & \frac{1}{1-\mu_2 \bar{\mu}_2} & \cdots & \frac{1}{1-\mu_2 \bar{\mu}_q} \\ \vdots & \vdots & \ddots & \vdots \\ \frac{1}{1-\mu_q \bar{\mu}_1} & \frac{1}{1-\mu_q \bar{\mu}_2} & \cdots & \frac{1}{1-\mu_q \bar{\mu}_q} \end{bmatrix} \otimes I_m. \quad (24)$$

Moreover, $\|\Xi_{\mu, \mu}\|^{1/2} \leq \frac{q\sqrt{m}}{\sqrt{1-\rho_\mu^2}}$, where $\rho_\mu = \max_{k=1, \dots, q} |\mu_k|$.

Hence, the theorem is proved by combining (22) with (23). \square

B. Asymptotic Bias Analysis

This subsection quantifies the bias between $G(z)$ and the asymptotic result $\check{G}^*(z)$ of the least-squares algorithm (14). For this purpose, we introduce the following additional assumptions:

- Assumption 3.** • The system $G(z)$ has no repeated poles.
• The poles of the system $G(z)$ are within a closed continuum $\mathcal{D} \subset \mathbb{D}$, where \mathcal{D} is known.

Remark 3. The assumption of no repeated poles is standard in the OBF literature [18, 20]. Furthermore, the assumption that the pole region \mathcal{D} is known based on a priori information is common in studies focusing on the pole selection algorithms for OBFs [20, 21].

As a result, the transfer function $G(z)$ of the system can be written in the following form [20, Chapter 11]:

$$G(z) = \sum_{j=1}^n \frac{R_j}{z - \lambda_j}, \quad R_j \in \mathbb{C}^{p \times m}, \quad (25)$$

where λ_j are the distinct poles of the system, and n denotes the number of poles.

Let $\Phi_u(\omega)$ denote the power spectral density (PSD) of the input signal u_t . Specifically,

$$\Phi_u(\omega) = \sum_{k=-\infty}^{\infty} R_u(k) e^{ik\omega},$$

where $R_u(k) = \mathbb{E}(u_t u_{t-k}^H)$ denotes the autocorrelation function of u_t .

The following theorem provides an upper bound on the asymptotic bias of the least-squares algorithm (14) using the bases $V_k(z)$ as the number of samples tends to infinity. The proof of the theorem is provided in Appendix II.

Theorem 6 (Asymptotic bias of the least-squares algorithm). *For a fixed group of bases $\{1/(z - \mu_k)\}_{k=1}^q$, the system approximation bias of G using the asymptotic solution of the least-squares problem $\check{G}^*(z) = \sum_{k=1}^q \frac{\check{R}_k^*}{z - \mu_k}$ satisfies the inequality*

$$\begin{aligned} \|\check{G}^*(z) - G(z)\|_2 &\leq \left[1 + \frac{\text{ess sup}_\omega \|\Phi_u(\omega)\|}{\text{ess inf}_\omega \|\Phi_u(\omega)\|} \right] \sum_{j=1}^n \frac{\|R_j\|}{\sqrt{1-|\lambda_j|^2}} \prod_{k=1}^q [\lambda_j, \mu_k]_h \\ &\leq \left[1 + \frac{\text{ess sup}_\omega \|\Phi_u(\omega)\|}{\text{ess inf}_\omega \|\Phi_u(\omega)\|} \right] \frac{\bar{R}}{\sqrt{1-\rho_\lambda^2}} \max_{j=1, \dots, n} \prod_{k=1}^q [\lambda_j, \mu_k]_h, \end{aligned} \quad (26)$$

where $\bar{R} = \sum_{j=1}^n \|R_j\|$ and $\rho_\lambda = \max_{j=1, \dots, n} |\lambda_j|$.

Remark 4. The \mathcal{H}_2 error bounds provided herein are consistent with the worst-case \mathcal{H}_2 identification and model reduction problems (see, e.g., [32, 33]), and resonate with mean-square robustness analyses in LTI systems (see, e.g., [34–37]), and hence are compatible with system analysis and synthesis in mean-square designs.

The upper bound in Theorem 6 can be decomposed into two components. The first component is determined by the intrinsic properties of the system (\bar{R}, ρ_λ) and the inputs in the collected data $(\Phi_u(\omega))$, while the second component depends on $\tau(\lambda, \mu) = \max_{j=1, \dots, n} \prod_{k=1}^q [\lambda_j, \mu_k]_h$, which is influenced by the choice of μ_k . Motivated by this observation, in the following section, we propose a pole selection algorithm that minimizes $\tau(\lambda, \mu)$, thereby reducing the asymptotic bias.

V. FUNDAMENTAL LOWER BOUND AND TSUJI POLE SELECTION ALGORITHM

This section focuses on *robustly*¹ selecting the poles μ_k by minimizing the worst-case identification bias across a class of systems, specifically, those whose poles lie within the pole region² \mathcal{D} , determined by *a priori* information. Additionally, we establish a fundamental lower bound on the worst-case identification bias and show that the Tsuji points asymptotically achieve this bound as the number of OBF poles q tends to infinity, demonstrating the optimality of the Tsuji pole selection algorithm.

The following minimax problem based on the pole region \mathcal{D} can be used to robustly select the optimal poles μ_k :

Problem 2 (Minimax pole selection problem [20, Chapter 11]).

$$\min_{\mu_1, \dots, \mu_q \in \mathcal{D}} \max_{\lambda \in \partial \mathcal{D}} \prod_{k=1}^q [\lambda, \mu_k]_h, \quad (27)$$

where $\partial \mathcal{D}$ denotes the boundary of \mathcal{D} .

Here the maximization is restricted to $\partial \mathcal{D}$ by the maximum-modulus principle, applied to the function $\lambda \mapsto \prod_{k=1}^q [\lambda, \mu_k]_h$.

However, for a general pole region \mathcal{D} , this minimax problem is equivalent to a semi-infinite programming problem [38], and is computationally challenging to solve. Instead, we propose to select the poles by solving the following maximization problem:

Problem 3 (Tsuji pole selection problem).

$$[\eta_{q1}, \dots, \eta_{qq}] = \arg \max_{\mu_1, \dots, \mu_q \in \partial \mathcal{D}} \prod_{1 \leq k < l \leq q} [\mu_k, \mu_l]_h, \quad (28)$$

where $\partial \mathcal{D}$ denotes the boundary of \mathcal{D} .

The solutions $\eta_{q1}, \dots, \eta_{qq}$ are called the q -th Tsuji points of the region \mathcal{D} introduced in Definition 2. The following theorem demonstrates the performance of the Tsuji points:

Theorem 7. Let $\eta_{q1}, \dots, \eta_{qq}$ denote the q -th Tsuji points of \mathcal{D} . Then, by choosing $\mu_k = \eta_{qk}$ for Problem 2, the

exponential decay rate of its objective function asymptotically approaches the hyperbolic Chebyshev constant $\tau(\mathcal{D})$ as $q \rightarrow \infty$, i.e.,

$$\lim_{q \rightarrow \infty} \max_{z \in \mathcal{D}} \left(\prod_{k=1}^q [z, \eta_{qk}]_h \right)^{1/q} = \tau(\mathcal{D}). \quad (29)$$

Proof. Suppose $\eta_{q1}, \dots, \eta_{qq}$ are the q -th Tsuji points of the set \mathcal{D} , i.e.,

$$\max_{\mu_1, \dots, \mu_q \in \mathcal{D}} \prod_{1 \leq k < l \leq q} [\mu_k, \mu_l]_h = \prod_{1 \leq k < l \leq q} [\eta_{qk}, \eta_{ql}]_h.$$

Then, for each $l = 1, \dots, q$, one can verify that

$$\phi_{-l} \triangleq \max_{z \in \mathcal{D}} \prod_{k=1, \dots, q, k \neq l} [z, \eta_{qk}]_h = \prod_{k=1, \dots, q, k \neq l} [\eta_{ql}, \eta_{qk}]_h.$$

Multiplying all ϕ_{-l} together, we can get that

$$\prod_{l=1}^q \phi_{-l} = \prod_{1 \leq k < l \leq q} ([\eta_{qk}, \eta_{ql}]_h)^2.$$

Therefore, there exists an ℓ with $1 \leq \ell \leq q$, such that

$$\phi_{-\ell} \leq \left(\prod_{l=1}^q \phi_{-l} \right)^{1/q} = \prod_{1 \leq k < l \leq q} ([\eta_{qk}, \eta_{ql}]_h)^{2/q}.$$

Consequently,

$$\begin{aligned} \max_{z \in \mathcal{D}} \left(\prod_{k=1}^q [z, \eta_{qk}]_h \right)^{1/q} &< (\phi_{-\ell})^{1/q} \\ &\leq \prod_{1 \leq k < l \leq q} ([\eta_{qk}, \eta_{ql}]_h)^{2/q^2}, \end{aligned}$$

where the first inequality is because $[z, \eta_{q\ell}]_h < 1$ for all $z, \eta_{q\ell} \in \mathbb{D}$. Let $q \rightarrow \infty$, we have that

$$\begin{aligned} \limsup_{q \rightarrow \infty} \max_{z \in \mathcal{D}} \left(\prod_{k=1}^q [z, \eta_{qk}]_h \right)^{1/q} &\leq \limsup_{q \rightarrow \infty} \max_{\mu_1, \dots, \mu_q \in \mathcal{D}} \left[[\mu_k, \mu_l]_h^{2/(q(q-1))} \right]^{1-1/q} = \tau(\mathcal{D}) \\ &= \lim_{q \rightarrow \infty} \min_{\mu_1, \dots, \mu_q} \max_{z \in \mathcal{D}} \left(\prod_{k=1}^q [z, \mu_k]_h \right)^{1/q} \\ &\leq \liminf_{q \rightarrow \infty} \max_{z \in \mathcal{D}} \left(\prod_{k=1}^q [z, \eta_{qk}]_h \right)^{1/q}. \end{aligned}$$

Hence, we conclude that

$$\lim_{q \rightarrow \infty} \max_{z \in \mathcal{D}} \left(\prod_{k=1}^q [z, \eta_{qk}]_h \right)^{1/q} = \tau(\mathcal{D}).$$

□

Finally, we leverage the results above to evaluate the worst-case identification bias for a group of systems consistent with *a priori* information, using the same set of bases determined by the proposed pole selection algorithm. Let \mathcal{G} denote this group of target systems whose poles lie

¹One possible approach is to *adaptively* select μ_k to be as close as possible to the true system poles λ_j based on the sampled data. However, in system identification, the values of λ_j are generally unknown. In Section VI, we show that identifying the true system poles becomes exponentially difficult as the system dimension increases.

²The pole region \mathcal{D} is a complex subset of the open unit disk that contains all true poles [20, Chapter 11].

within the region \mathcal{D} and whose coefficient magnitude satisfies $\sum_{j=1}^n \|R_j\| \leq \bar{R}$. Since we expect an exponential decay as q increases, we focus on the following term:

$$\liminf_{q \rightarrow \infty} \max_{G \in \mathcal{G}} \min_{\check{R}_1, \dots, \check{R}_q} \left\| G - \sum_{k=1}^q \frac{\check{R}_k}{z - \mu_k} \right\|_2^{1/q}. \quad (30)$$

Theorem 8 (Fundamental limit on the worst-case approximation bias). *For any sequence of the selected poles $\{\mu_k\}$,*

$$\liminf_{q \rightarrow \infty} \max_{G \in \mathcal{G}} \min_{\check{R}_1, \dots, \check{R}_q} \left\| G - \sum_{k=1}^q \frac{\check{R}_k}{z - \mu_k} \right\|_2^{1/q} \geq \tau(\mathcal{D}), \quad (31)$$

where $\tau(\cdot)$ is the hyperbolic Chebyshev constant introduced in Definition 1.

On the other hand, when $\{\mu_k\}$ are chosen as the q -th Tsuji points $\eta_{q1}, \dots, \eta_{qq}$ of \mathcal{D} , the following equality holds:

$$\lim_{q \rightarrow \infty} \max_{G \in \mathcal{G}} \min_{\check{R}_1, \dots, \check{R}_q} \left\| G - \sum_{k=1}^q \frac{\check{R}_k}{z - \eta_{qk}} \right\|_2^{1/q} = \tau(\mathcal{D}). \quad (32)$$

The proof of the theorem is reported in Appendix II.

Theorem 8 establishes a fundamental limit, proving that no pole selection algorithm can achieve a worst-case approximation bias with a decay rate faster than $O((\tau(\mathcal{D}) - \epsilon)^q)$ for any $\epsilon > 0$.

On the other hand, the theorem also proves that the Tsuji points, which are the solution to the proposed maximization problem (28), asymptotically achieve this limit. Consequently, our Tsuji pole selection approach is asymptotically optimal while avoiding the computationally expensive minimax formulation.

A. Initialization Strategy

In the preceding discussion, we have simplified a minimax problem to a maximization problem, whose solution is asymptotically optimal. However, Problem 3 remains non-convex in general, and thus the initial choice of μ_k may affect the optimization result. To effectively solve Problem 3, we propose an *initialization strategy* for the optimization problem.

Let f denote a conformal mapping that transforms the annulus $\mathbb{D} \setminus \bar{\mathbb{D}}_{\tau(\mathcal{D})} = \{z \mid \tau(\mathcal{D}) < |z| < 1\}$ to $\mathbb{D} \setminus \mathcal{D}$, such that $|z| = \tau(\mathcal{D})$ corresponds to $\partial\mathcal{D}$. The existence and computation of this mapping can be found in [39]. When \mathcal{D} is a real interval $[-\rho, \rho]$, $\rho < 1$, the analytical solution of its conformal mapping is provided in Appendix III.

The proposed *initialization strategy* to solve Problem 3 is summarized as follows:

- 1) **Find the conformal mapping** on the complex plane $f : \mathbb{D} \rightarrow \mathbb{D}$ that maps the annulus $\mathbb{D} \setminus \bar{\mathbb{D}}_{\tau(\mathcal{D})}$ to the open set $\mathbb{D} \setminus \mathcal{D}$.
- 2) **Uniformly sample q points** $\tau(\mathcal{D})e^{2k\pi i/q}$, $k = 1, \dots, q$ on the inner disk $\bar{\mathbb{D}}_{\tau(\mathcal{D})} = \{z \in \mathbb{C} \mid |z| \leq \tau(\mathcal{D})\}$.

Fig. 1: Visualization of the introduced initialization strategy of the Tsuji points given the pole region \mathcal{D} . f in the figure denotes the conformal mapping from the annulus $\mathbb{D} \setminus \bar{\mathbb{D}}_{\tau(\mathcal{D})}$ to $\mathbb{D} \setminus \mathcal{D}$ (the gray regions).

- 3) **Map the sampled points** to the pole region \mathcal{D} via the conformal mapping $f(\cdot)$, i.e., $\tilde{\eta}_{qk} = f(\tau(\mathcal{D})e^{2k\pi i/q})$, $k = 1, \dots, q$.

The resulting $\tilde{\eta}_{qk}$ are the initializations to the Tsuji points.

The initialization procedure when \mathcal{D} is an ellipse inside the unit circle is visualized in Fig. 1. The rationale behind this strategy is that $\tilde{\eta}_{q1}, \dots, \tilde{\eta}_{qq}$ asymptotically converge to the Tsuji points when $\partial\mathcal{D}$ is an analytic Jordan curve, as shown by the following result:

Proposition 9 (Distribution of Tsuji points; see Theorem 2 in [40] and equation (3) in [41]). *Denote $\eta_{q1}, \dots, \eta_{qq}$ as the q -th Tsuji points of \mathcal{D} , and let ν_k be points such that $f(\tau(\mathcal{D})e^{i\nu_k}) = \eta_{qk}$, $k = 1, \dots, q$, then*

$$\left| \nu_k - \frac{2\pi k}{q} \right| \leq L \frac{(\log q)^{3/2}}{q}, \quad k = 1, \dots, q, \quad (33)$$

where $L > 0$ is independent of q and k .

The proposed pole selection algorithm with the initialization strategy is summarized as follows. Suppose we have found the explicit form of the conformal mapping f .

- 1) **Initialize** $\nu_k = 2k\pi/q$.
- 2) **Solve the following maximization problem:**

$$\max_{\nu_1, \dots, \nu_q \in [0, 2\pi]} \prod_{1 \leq k < l \leq q} [f(e^{i\nu_k}), f(e^{i\nu_l})]_{\text{h}}, \quad (34)$$

where the optimal solutions are denoted as ν_1^*, \dots, ν_q^* .

- 3) The **Tsuji points** are $\nu_{qk} = f(e^{i\nu_k^*})$.

VI. HARDNESS OF PRECISE POLE IDENTIFICATION

The previous section proposes a *robust* pole selection algorithm by minimizing the worst-case identification bias across a group of systems. However, for identifying a single system, a more direct approach is to *adaptively* select the poles μ_k to approximate the true system poles λ_j as closely as possible based on sampled data.

In this section, we show that for an LTI system whose transfer function has a denominator of degree n , the number of samples required to distinguish the true system from the *robust solution* in the previous section grows exponentially with n . Furthermore, we extend this result to a state-space formulation, proving that the sample complexity for distinguishing the true state-space model of order n from the *robust solution* of order n grows exponentially with

$\underline{n} \triangleq \lfloor \frac{n}{\min(p,m)} \rfloor$. Consequently, identifying the true system poles λ_j becomes exponentially challenging as the system's dimension increases.

Specifically, suppose the true system has the dynamics (8). Besides Assumption 1, 2 and 3, for technical simplicity, we impose additionally

- Assumption 4.** • The noise $\{v_t\}$ is i.i.d. and Gaussian distributed, i.e., $v_t \sim \mathcal{N}(0, \mathcal{R})$ with $\mathcal{R} \succ 0$.
- The samples are collected starting from time 0, and the system inputs from time $-\infty$ to -1 are kept at 0.
 - The system input is a stationary process and its power spectral density is bounded, i.e., $\text{ess sup}_\omega \|\Phi_u(\omega)\| < \infty$.

Then, the transfer function $G(z)$ can be similarly decomposed as in (25). We next use the robust solution in the previous section to construct a surrogate system \tilde{G} as follows:

- The poles μ_1, \dots, μ_n are fixed as the minimizer of Problem 2 in Section V;
- The parameters $\tilde{R}_1, \dots, \tilde{R}_n$ are chosen as the optimal solution of Problem 1.

Here, we keep the dimension of the surrogate system the same as the true system for the fairness of comparison. The constructed surrogate system \tilde{G} can be written as

$$\tilde{G}(z) = \sum_{k=1}^n \frac{\tilde{R}_k}{z - \mu_k}. \quad (35)$$

In what follows, we establish the aforementioned sample complexity bound via distinguishing the distributions of $y_1, \dots, y_N, u_0, \dots, u_{N-1}$ under the following two hypotheses:

$$\begin{aligned} \mathcal{H}_0 : \{y_t, u_{t-1}\}_{t=1}^N &\text{ are from the true system } G, \\ \mathcal{H}_1 : \{y_t, u_{t-1}\}_{t=1}^N &\text{ are from the surrogate system } \tilde{G}. \end{aligned} \quad (36)$$

Let \mathbb{P}_0 and \mathbb{P}_1 denote the conditional distribution of $\{y_t\}_{t=1}^N$ given $\{u_t\}_{t=0}^{N-1}$ in the two hypotheses \mathcal{H}_0 and \mathcal{H}_1 respectively. Here, we use the KL divergence between the distributions of the system outputs y_t given the same inputs u_t as a metric on the difficulty of distinguish the true system G from the surrogate system \tilde{G} . The following theorem shows that the sample complexity for distinguishing the two systems, i.e., reach a constant KL divergence requirement, grows exponentially with n . The proof of the theorem is reported in Appendix V.

Theorem 10. *The expected³ KL divergence between the two distributions in (36) satisfies*

$$\mathbb{E}D_{\text{KL}}(\mathbb{P}_0 \parallel \mathbb{P}_1) \leq \frac{\bar{R}^2 \|\mathcal{R}^{-1}\| \text{ess sup}_\omega \|\Phi_u(\omega)\|}{2(1 - \rho_\lambda^2)} \tau_n(\mathcal{D})^{2n} N, \quad (37)$$

where ρ_λ is the spectral radius of the true system G , \mathcal{R} is the covariance matrix of the noise in Assumption 4, $\bar{R} = \sum_{j=1}^n \|R_j\|$ is the modified system energy with slight abuse

of notations and $\tau_n(\mathcal{D})$ is the finite hyperbolic Chebyshev constant of the region \mathcal{D} defined in Definition 1.

Moreover, given a constant $\delta > 0$, in order to distinguish the two hypotheses in (36) with the KL divergence no smaller than δ , N satisfies

$$N \geq \frac{2\delta(1 - \rho_\lambda^2)}{\bar{R}^2 \|\mathcal{R}^{-1}\| \text{ess sup}_\omega \|\Phi_u(\omega)\|} \tau_n(\mathcal{D})^{-2n}.$$

When the system dimension n tends to infinity,

$$\liminf_{n \rightarrow \infty} N^{1/(2n)} \geq \tau(\mathcal{D})^{-1}.$$

Theorem 10 shows that the number of samples required to distinguish the true system from the surrogate system grows exponentially with the system dimension n , even though the two systems have entirely distinct poles. This result implies that identifying the true system poles becomes exponentially more challenging as the system dimension increases.

Remark 5. Note that $\tau_n(\mathcal{D})$ converges to the hyperbolic Chebyshev constant of \mathcal{D} , which is less than 1 for a strictly stable system. Consequently, the sample complexity grows exponentially with n . Moreover, as is illustrated by Lemma 4, if the region of poles \mathcal{D} is a real interval, $\tau(\mathcal{D})$ is usually small, and the sample complexity grows exponentially with n at a fast speed. For example, even when $\mathcal{D} = [-0.999, 0.999]$, $N \sim \mathcal{O}(1.81^n)$.

Remark 6. The result can be generalized to unstable systems by establishing the hardness on the identification of the stable subsystem. To be specific, by partial fraction decomposition, the transfer function matrix $G(z)$ can be rewritten into

$$G(z) = G_s(z) + G_n(z),$$

where $G_s(z)$ contains all the stable poles and $G_n(z)$ contains all the unstable or marginally stable poles. Even if $G_n(z)$ is perfectly known from an oracle, which simplifies the identification problem, we can still consider the modified system output

$$\tilde{y}_t = y_t - G_n(z)u_t = G_s(z)u_t + v_t,$$

and the sample complexity of the identification has a lower bound defined by the sample complexity of the stable subsystem.

Additionally, motivated by recent studies highlighting the ill-conditioned nature of state-space model identification [42, 43], we extend our results to state-space models. The proof of this corollary appears in Appendix V.

Corollary 11. Recall that $\underline{n} = \lfloor \frac{n}{\min(p,m)} \rfloor$. For any n -dimensional state-space model with m inputs, p outputs and parameters A, B, C , whose corresponding transfer function G and the observation noises satisfy Assumption 1, 3 and Assumption 4, there exists a corresponding n -dimensional state-space realization of the constructed \tilde{G} , such that the sample complexity for differentiating the two hypotheses in (36) with the KL divergence no smaller than δ satisfies

$$\liminf_{n \rightarrow \infty} N^{1/(2\underline{n})} \geq \tau(\mathcal{D})^{-1}. \quad (38)$$

³The expectation is taken with respect to the persistent exciting input u_t .

Remark 7. *Theorem 10 and Corollary 11 indicate that any algorithm attempting to estimate the true pole locations from finite noisy data, including both classical state-space identification methods such as Ho-Kalman and MOESP and more recent approaches that aim to recover state-space parameters from input-output trajectories [44, 45], may be intrinsically ill-conditioned, particularly as the system dimension increases.*

VII. SIMULATIONS

This section provides numerical examples to verify the derived bounds and illustrate the effectiveness of the proposed pole selection algorithm.

We begin by testing the performance of the pole selection algorithm in identifying the system

$$G(z) = \frac{0.0247z + 0.0355}{\prod_{j=1}^4 (z - \lambda_j)}, \quad (39)$$

using q OBFs, where

$$\begin{aligned} \lambda_1 &\sim \mathcal{N}(0, 0.02^2), \lambda_2 \sim \mathcal{N}(0, 0.02^2), \\ \lambda_3 &\sim \mathcal{N}(0.9048, 0.02^2), \lambda_4 \sim \mathcal{N}(0.3679, 0.02^2). \end{aligned}$$

Moreover, all poles λ_j are projected back to the interval $[-0.95, 0.95]$, which is used as *a priori* information. The expected location of the true poles and the numerator of the transfer function in (39) are chosen according to the system used in [28, 46]. we further add noise to the true poles to test the robustness of the pole selection algorithms. A total of 100 independent experiments are conducted.

We apply the following pole selection algorithms to the perturbed systems:

- *Minimax method [20]:* The minimax optimization problem (Problem 2) is solved using MATLAB's minimax solver `fminimax`, assuming the pole region is $\mathcal{D} = [-0.95, 0.95]$.
- *SQP method [47]:* The min-max pole selection problem (Problem 2) is solved using a multi-start Sequential Quadratic Programming (SQP) approach implemented via MATLAB's `fmincon`, following [47, Chapter 3.4.1, Algorithm 1], with pole region $\mathcal{D} = [-0.95, 0.95]$.
- *RA method [47]:* The min-max pole selection problem (Problem 2) is solved using the Randomized Algorithm (RA) introduced in [47, Chapter 3.4.2, Algorithm 3], based on probabilistic performance verification and bisection search, with pole region $\mathcal{D} = [-0.95, 0.95]$.
- *Greedy method [28]:* This method selects poles sequentially in an adaptive manner. At each iteration, it computes the *residual function*, defined as the part of the true system's transfer function that is not yet captured by the previously selected OBF bases. The algorithm then chooses the pole whose associated basis function is most aligned with this residual in the \mathcal{H}_2 sense, updates the residual accordingly, and repeats. In our implementation, the true system transfer function is used directly as the nominal system (39).

- *Initial guess of Tsuji points:* The initial Tsuji points are calculated using the method in Section V and Appendix III, with pole region $\mathcal{D} = [-0.95, 0.95]$.
- *Tsuji points:* The Tsuji points are solved by the maximization Problem 3 using the previously calculated initial guess.

Performance of identification is measured using the relative asymptotic \mathcal{H}_2 bias, defined as the ratio between the optimal value of Problem 1 and the \mathcal{H}_2 norm of the true system $\|G(z)\|_2$.

Fig. 2 shows the relative \mathcal{H}_2 approximation bias versus the number of poles q . The figure demonstrates that the asymptotic approximation bias of our Tsuji pole selection algorithm decreases exponentially with the number of basis functions, confirming the theoretical results from Section IV.

To further interpret the observed trends in Fig. 2, we compare the behavior of different pole selection methods. Several numerical solvers, including minimax optimization, SQP, and RA, are designed to approximate the global solution of the minimax pole selection problem characterized by Problem 2. It can be observed that for a moderate number of bases, these optimization methods are more likely to attain the global optimum of the minimax problem, and when this occurs, the resulting approximation errors are very small. This behavior is evident for $q = 10$, where the minimax-based solution achieves the smallest approximation bias among all methods. As the number of bases increases, however, the optimization problem becomes more nonconvex and sensitive to initialization, leading to degraded performance and increased variability across Monte Carlo trials. For $q = 15$, the minimax-based solvers exhibit noticeably larger worst-case errors. In contrast, the Tsuji points remain stable and consistently achieve small *worst-case* asymptotic biases.

From a robustness perspective, the worst-case approximation bias is a more meaningful metric than best-case performance, since all methods may occasionally achieve small errors when the selected basis poles happen to be well aligned with the dominant poles of the true system, especially for low-dimensional systems. In this sense, the Tsuji-based methods consistently exhibit small and stable *worst-case* asymptotic biases, which aligns well with their theoretical design objective of minimizing the worst-case approximation error.

Next, to further demonstrate the effectiveness of the proposed method, we examine the identification of a higher-order system. Consider a heat diffusion process [48] in a (3×3) m square region with internal obstacles, as shown in Fig. 3. The two small circles are centered at $(0.75, 2.25)$ and $(2.25, 0.75)$ respectively, each with a radius of 0.1m. Additionally, a half-circle obstacle is centered at $(1.5, 0.95)$ with a radius of 0.55m.

We denote the temperature at (x, y) and time t by $s(x, y, t)$, and the dynamics of the diffusion process in the square region are characterized by the following Partial

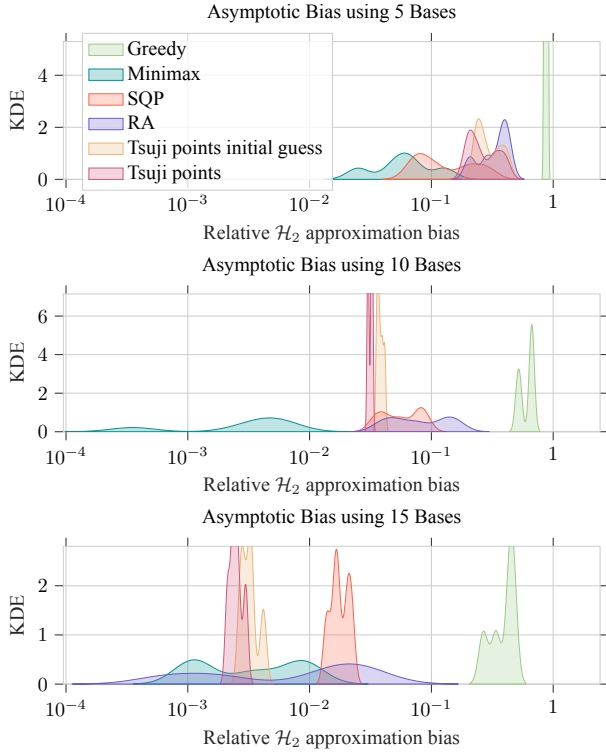

Fig. 2: Asymptotic relative \mathcal{H}_2 approximation bias of the nominal system (39) under Gaussian perturbations of the true system poles, visualized using a multi-kernel density estimate (KDE).

Fig. 3: The shape of the region considered in the diffusion process. The obstacles are shown in grey, the heat sources are denoted as \times , and the sensor is denoted as the black dot.

Differential Equation (PDE):

$$\frac{\partial s}{\partial t} = \alpha(x, y) \left(\frac{\partial^2 s}{\partial x^2} + \frac{\partial^2 s}{\partial y^2} \right), \quad (40)$$

with the boundary condition

$$s(x, y, t) = 0, \quad \forall (x, y) \in \mathcal{B},$$

where $\alpha(x, y)$ denotes the diffusion constant at (x, y) , and \mathcal{B} represents the boundary of the region. A heat source is located at $(1.5, 2.25)$ and is set to a temperature $u_k \sim \mathcal{N}(0, 1)$ at each time step. A sensor is positioned at $(1.5, 1.5)$. The system is further discretized on a 10×10 grid following the method in [48]. The experiment is repeated 100 times, with each instance introducing element-wise Gaussian perturbations to the system matrix A (standard deviation of 10^{-3}) to account for factors like medium heterogeneity.

We apply all six pole selection methods used in the previous experiment for simulation, keeping the same configurations, except that the pole region is now set to $\mathcal{D} = [-0.99, 0.99]$. Although \mathcal{D} is specified as a real interval, the true poles of the system can be complex and lie outside \mathcal{D} due to the perturbations in A , making the *a priori* information inaccurate.

The simulation results are shown in Fig. 4. For this high-dimensional system, OBFs with poles selected by the minimax, SQP, RA, and greedy methods exhibit relatively large asymptotic biases, together with increased variability across trials. In contrast, the Tsuji points achieve the smallest asymptotic bias using only 15 bases for the 100-dimensional system and exhibit consistently robust performance, further highlighting the effectiveness of the proposed approach in high-dimensional settings.

Compared with case with the lower-dimensional system, the advantage of the Tsuji-based pole selection becomes more pronounced in the high-dimensional setting. In low-dimensional systems, small approximation errors may occasionally be observed due to incidental alignment between the selected basis poles and the dominant poles of the true system. As the system dimension increases, such favorable alignment becomes increasingly unlikely, and the consistently small average and worst-case asymptotic biases achieved by the Tsuji points highlight their robustness, especially in high-dimensional systems.

Additionally, we compare the computation time of all pole selection methods as a function of the number of bases q , with the results reported in Fig. 5. The initial guess of the Tsuji points exhibits the shortest computation time among all approaches, while the RA method also demonstrates competitive efficiency. The Tsuji points method is slightly slower but remains in the same order of magnitude. Notably, the runtimes of these three methods are all below 10^{-2} seconds and do not increase noticeably as q grows. In contrast, the remaining minimax, SQP and greedy methods incur higher computational costs and exhibit an increase in runtime for larger q . Overall, these results indicate that the proposed Tsuji pole selection achieves a favorable trade-off between approximation accuracy and computational efficiency, particularly in regimes with larger numbers of bases.

To further validate the convergence rate derived in Theorem 5, we solve the least-squares problem in (14) to identify both previously considered systems. We use 10 OBFs, each configured with Tsuji points computed for the respective pole region. A total of 100 experiments are conducted with 500 time steps each. The relative \mathcal{H}_2 identification bias as a function of time step is plotted in Fig. 6, confirming the convergence rates in Theorem 5. For comparison, Fig. 6 also reports the identification error of the Ho-Kalman algorithm, implemented as in [44] with system dimension $n = 10$ and $T = 30$. The results show that the Ho-Kalman algorithm exhibits considerably larger finite-sample identification error for both systems, consistent with results reported in the literature [10, 11]. This further illustrates that the OBF-based method achieves more reliable identification performance in

finite-sample regimes.

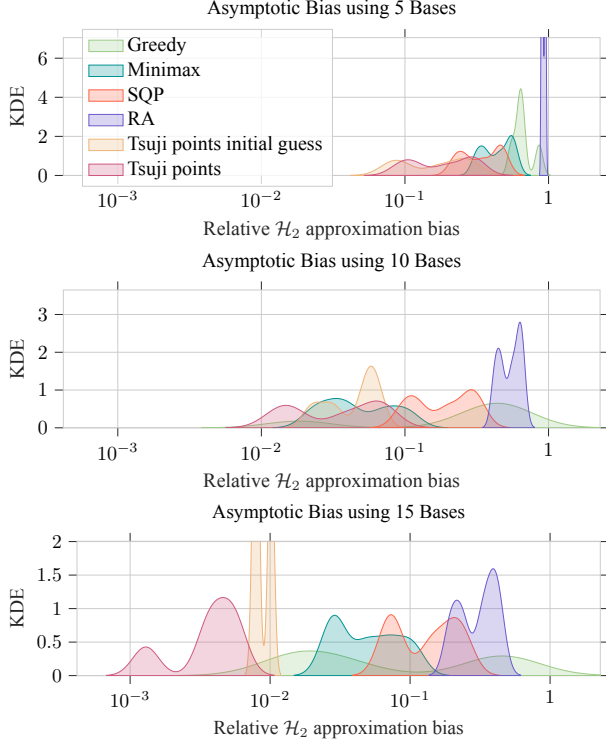

Fig. 4: Asymptotic relative \mathcal{H}_2 approximation bias of the diffusion process under Gaussian perturbations of the true system poles, visualized using a multi-kernel density estimate (KDE).

VIII. CONCLUSION

This paper analyzes the performance of the OBF method, showing that the identification error under \mathcal{H}_2 norm using the OBF method with N samples converges to an asymptotic bias almost surely at the rate of $O(N^{-0.5})$. Additionally, we establish an upper bound on this bias, given by $\bar{\alpha}\tau(\lambda, \mu)$, where $\tau(\lambda, \mu)$ denotes the distance between the true system poles λ and the OBF poles μ . While the bound suggests that the ideal choice of OBF poles would match the true system poles, we prove that identifying the true poles becomes exponentially challenging as system dimension increases. To address this, we propose the Tsuji pole selection algorithm, which minimizes the worst-case identification bias across a specified class of systems. We further demonstrate that these selected poles achieve a fundamental bound on worst-case identification bias and provide an algorithm to compute near-optimal initial points for the maximization problem, mitigating issues of local minima. Numerical results validate the derived bounds and demonstrate the effectiveness of the proposed Tsuji pole selection algorithm.

APPENDIX I PROOF OF LEMMA 4

We first introduce the following two lemmas:

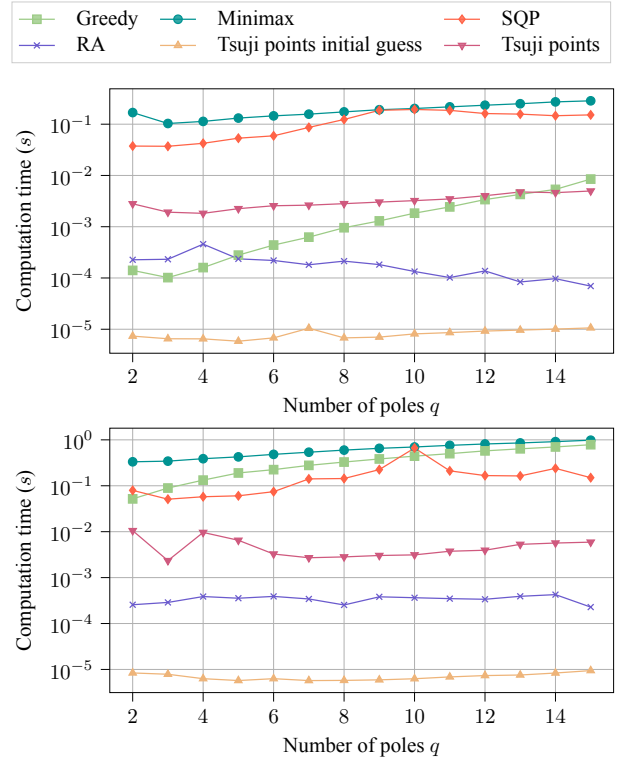

Fig. 5: Computation time versus the number of basis poles q for different pole selection algorithms, evaluated on pole regions $\mathcal{D} = [-0.95, 0.95]$ (top) and $\mathcal{D} = [-0.99, 0.99]$ (bottom).

Lemma 12 (Hyperbolic Chebyshev Constant of real intervals; see page 278 in [30]). *The hyperbolic Chebyshev constant of the real interval $[0, \rho]$, $\rho < 1$ is*

$$\tau([0, \rho]) = \exp \left\{ -\frac{\pi}{2} \frac{K(\sqrt{1-\rho^2})}{K(\rho)} \right\},$$

where

$$K(\rho) = \int_0^1 \frac{dx}{\sqrt{(1-x^2)(1-\rho^2 x^2)}}.$$

Lemma 13 (Invariance under conformal mapping; see page 278 in [30]). *Let \mathcal{D} and $\tilde{\mathcal{D}}$ be two distinct closed subsets of the open unit disk \mathbb{D} . Let \mathcal{F} be the family of conformal mapping f of $\mathbb{D} \setminus \mathcal{D}$ onto $\mathbb{D} \setminus \tilde{\mathcal{D}}$ bordering on the unit circle, such that $f(\partial\mathbb{D}) = \partial\mathbb{D}$. Then*

$$\tau(\tilde{\mathcal{D}}) = \tau(\mathcal{D})$$

for all $f \in \mathcal{F}$.

Then, we are ready to prove the results in Lemma 4.

Proof. Statement 1 is proved by [30] and is omitted here for simplicity.

For statement 2, according to Lemma 13, we aim to seek the corresponding conformal mapping that maps the interval $[\rho_1, \rho_2]$ to $[0, \tilde{\rho}]$. Then, Lemma 12 can be applied to obtain the hyperbolic Chebyshev constant of the interval $[\rho_1, \rho_2]$.

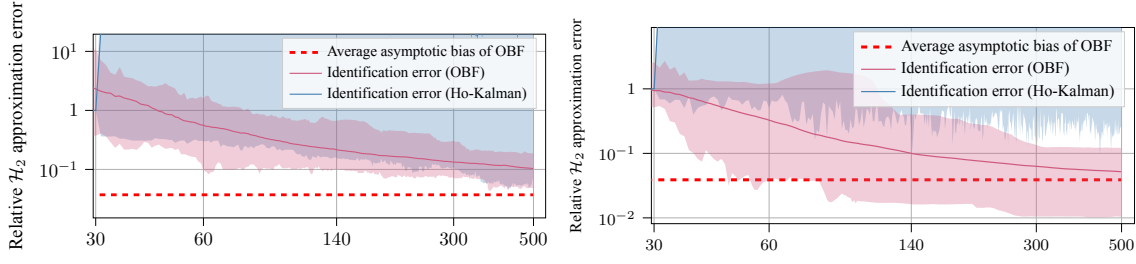

Fig. 6: Online relative \mathcal{H}_2 identification error of the system (39) (left) and the diffusion process (right). Results are shown for OBF-based identification using 10 basis functions with Tsuji points, as well as for the Ho-Kalman algorithm. The plot reports 100 Monte Carlo experiments, where the solid line denotes the mean identification error at each time step and the shaded area indicates the range of errors across experiments.

One can verify that the following conformal mapping satisfies our requirements:

$$f(z) = \frac{z - \rho_1}{1 - \bar{\rho}_1 z},$$

and $f(\rho_1) = 0$. Therefore,

$$\tilde{\rho} = f(\rho_2) = \frac{\rho_2 - \rho_1}{1 - \rho_1 \rho_2}.$$

Finally, using Lemma 12, statement 2 is proved. \square

APPENDIX II

PROOF OF THEOREM 6 AND THEOREM 8

We briefly outline our main idea for quantifying the asymptotic bias in Theorem 6. The bias between $G(z)$ and $\tilde{G}^*(z)$ is influenced by two factors: the statistical properties of the input signal u_t and the approximation bias of the system $G(z)$ using the bases $V_k(z)$. To analyze the asymptotic bias, we first isolate the effect of u_t by introducing a medium system $\tilde{G}(z)$ where u_t is i.i.d. white noise with zero mean and unit covariance:

$$\tilde{R}_1^*, \dots, \tilde{R}_q^* = \arg \min_{\tilde{R}_1, \dots, \tilde{R}_q} \left\| G(z) - \sum_{k=1}^q \tilde{R}_k V_k(z) \right\|_2, \quad (41)$$

$$\tilde{G}(z) = \sum_{k=1}^q \tilde{R}_k^* V_k(z), \quad G_e(z) = G(z) - \tilde{G}(z). \quad (42)$$

The system $\tilde{G}(z)$ also serves as the optimal solution to Problem 1. Using $\tilde{G}(z)$, we can now quantify the bias between $\tilde{G}^*(z)$ and $G(z)$ by first establishing the relationship between $\|\tilde{G}^*(z) - G(z)\|_2$ and $\|G_e(z)\|_2$, which captures the influence of the input signal u_t . We then proceed to quantify the asymptotic bias $\|G_e(z)\|_2$.

The following proposition provides an upper bound on the asymptotic bias between $\tilde{G}^*(z)$ and $G(z)$ in terms of $G_e(z)$:

Proposition 14 (Asymptotic bias with arbitrary inputs; following Proposition 6.3 in [16]). *Suppose the noise sequence $\{v_k\}$ is a martingale difference sequence. Then, the asymptotic approximation bias between the solution of the least-squares problem (14), $\tilde{G}^*(z)$, and the true system $G(z)$ satisfies*

$$\|\tilde{G}^*(z) - G(z)\|_2 \leq \left[1 + \frac{\text{ess sup}_\omega \|\Phi_u(\omega)\|}{\text{ess inf}_\omega \|\Phi_u(\omega)\|} \right] \|G_e(z)\|_2, \quad (43)$$

where $G_e(z)$ is defined in (42) and $\tilde{G}^*(z)$ is introduced in (16).

Proposition 14 isolates the effect of the input signal u_t on the approximation bias, enabling us to focus on $G_e(z)$. The following lemma provides an upper bound on $\|G_e(z)\|_2$.

Lemma 15 (Optimal \mathcal{H}_2 approximation bias with fixed μ_k). *For a fixed group of bases $\{1/(z - \mu_k)\}_{k=1}^q$, the optimal \mathcal{H}_2 approximation bias $G_e(z)$ of G using any linear combination of these bases is bounded by*

$$\|G_e(z)\|_2 \leq \sum_{j=1}^n \frac{\|R_j\|}{\sqrt{1 - |\lambda_j|^2}} \prod_{k=1}^q [\lambda_j, \mu_k]_h, \quad (44)$$

where R_j and λ_j are defined in (25).

To prove Lemma 15, we first prove the following theorem:

Theorem 16. *Let scalars $r_1, \dots, r_q \in \mathbb{C}$. For an arbitrary $\lambda \in \mathbb{D}, \forall \mu_1, \dots, \mu_q \in \mathbb{D}$ and $\mu_j \neq \mu_k, \forall j \neq k$, then the relative approximation error of $\frac{1}{z - \lambda}$ using the linear combination of $\frac{1}{z - \mu_1}, \dots, \frac{1}{z - \mu_q}$ satisfies*

$$\min_{r_1, \dots, r_q} \frac{\left\| \frac{1}{z - \lambda} - \sum_{k=1}^q \frac{r_k}{z - \mu_k} \right\|_2}{\left\| \frac{1}{z - \lambda} \right\|_2} = \prod_{k=1}^q [\lambda, \mu_k]_h, \quad (45)$$

where $[\cdot, \cdot]_h$ denotes the pseudohyperbolic metric defined in (1).

Proof. The case where $\exists k, \lambda = \mu_k$ is trivially true since both sides of (45) are 0. Thus, we only consider the situation when $\lambda \neq \mu_k, \forall k = 1, \dots, q$. We first consider the case where $\lambda \neq 0$, and $\mu_k \neq 0, \forall k = 1, \dots, q$. The least-squares error can be written as:

$$\min_{r_1, \dots, r_q} \left\| \frac{1}{z - \lambda} - \sum_{k=1}^q \frac{r_k}{z - \mu_k} \right\|_2^2 = \phi_{\lambda, \lambda} - p_{\lambda, \mu} \Xi_{\mu, \mu}^{-1} p_{\lambda, \mu}^H, \quad (46)$$

where

$$\phi_{\lambda, \lambda} = \left\langle \frac{1}{z - \lambda}, \frac{1}{z - \lambda} \right\rangle = \frac{1}{1 - |\lambda|^2},$$

and similarly,

$$p_{\lambda, \mu} = \begin{bmatrix} \frac{1}{1 - \lambda \bar{\mu}_1} & \frac{1}{1 - \lambda \bar{\mu}_2} & \dots & \frac{1}{1 - \lambda \bar{\mu}_q} \end{bmatrix},$$

and $\Xi_{\lambda,\mu}$ is defined in (24). Denote

$$\tilde{\Xi} \triangleq \begin{bmatrix} \phi_{\lambda,\lambda} & p_{\lambda,\mu} \\ p_{\lambda,\mu}^H & \Xi_{\mu,\mu} \end{bmatrix}.$$

Then one can verify that

$$\tilde{\Xi} = D_{\lambda,\mu} \Xi_{\lambda,\mu}, \quad (47)$$

where

$$D_{\lambda,\mu} = \text{diag} \left(\frac{1}{\lambda}, \frac{1}{\mu_1}, \dots, \frac{1}{\mu_q} \right),$$

$$\Xi_{\lambda,\mu} = \begin{bmatrix} \frac{1}{1/\lambda - \bar{\lambda}} & \frac{1}{1/\lambda - \bar{\mu}_1} & \dots & \frac{1}{1/\lambda - \bar{\mu}_q} \\ \frac{1}{1/\mu_1 - \bar{\lambda}} & \frac{1}{1/\mu_1 - \bar{\mu}_1} & \dots & \frac{1}{1/\mu_1 - \bar{\mu}_q} \\ \vdots & \vdots & \ddots & \vdots \\ \frac{1}{1/\mu_q - \bar{\lambda}} & \frac{1}{1/\mu_q - \bar{\mu}_1} & \dots & \frac{1}{1/\mu_q - \bar{\mu}_q} \end{bmatrix}.$$

Notice that $\Xi_{\lambda,\mu}$ is a Cauchy matrix, and is invertible since μ_k are distinct to each other and $\lambda \neq \mu_k$. Moreover, by block matrix inversion lemma, the top left entry of $\tilde{\Xi}^{-1}$ is $[\tilde{\Xi}^{-1}]_{1,1} = (\phi_{\lambda,\lambda} - p_{\lambda,\mu} \Xi_{\mu,\mu}^{-1} p_{\lambda,\mu}^H)^{-1}$. Thus, we can obtain the LHS in the theorem by considering the inversion of $\tilde{\Xi}$:

$$\begin{aligned} & \phi_{\lambda,\lambda} - p_{\lambda,\mu} \Xi_{\mu,\mu}^{-1} p_{\lambda,\mu}^H \\ &= \frac{\prod_{k=1}^q (1/\lambda - 1/\mu_k) (\bar{\mu}_k - \bar{\lambda})}{(1 - |\lambda|^2) \prod_{k=1}^q (1/\lambda - \bar{\mu}_k)(1/\mu_k - \bar{\lambda})} \quad (48) \\ &= \frac{1}{1 - |\lambda|^2} \prod_{k=1}^q \left| \frac{\mu_k - \lambda}{1 - \bar{\mu}_k \lambda} \right|^2. \end{aligned}$$

Equation (48) leverages the explicit form of the Cauchy matrix inversion [49].

Next, we consider the case where $\lambda = 0$ or $\mu_k = 0$, but λ and μ_k are still distinct from each other. In this case, the decomposition (47) no longer exists. However, one can prove that the matrix $\Xi_{\mu,\mu}$ and $\tilde{\Xi}$ are still invertible. Thus, the error equation (46) still holds. Moreover, since matrix inverse $\tilde{\Xi}^{-1}$ is differentiable w.r.t. matrix elements, we can see that $[\tilde{\Xi}^{-1}]_{1,1}$ is continuous w.r.t. λ and μ_k . Thus, the result in (48) still holds when $\lambda = 0$ or $\mu_k = 0$. \square

Remark 8. Equation (4.48) in [20] provides a pointwise bound on the frequency-response error $|G_e(e^{i\omega})|$ on the unit circle. Integrating this pointwise bound over the unit circle yields an \mathcal{H}_2 -type bound that is equivalent to Lemma 15. Related continuous-time variants are also discussed in [50]. Here, we introduce an alternative proof that utilizes the inner product and the inversion of the Cauchy matrix to derive the discrete-time result.

Remark 9. The approximation bias of $1/(z - \lambda)^l, l > 1$ using $1/(z - \mu_k), k = 1, \dots, q$ can be similarly derived using this method. Essentially, the difference lies in the form of the covariance matrix $\tilde{\Xi}$, which also contains the partial derivative of λ to the current $\tilde{\Xi}$. Thus, the explicit form of the matrix inverse $\tilde{\Xi}^{-1}$ and the resulting approximation error may be further derived for a fixed l .

Next, we are ready to prove Lemma 15.

Proof. The objective function of Problem 1 has the following upper bound:

$$\|G_e(z)\|_2 \leq \min_{\tilde{r}_{11}, \dots, \tilde{r}_{qn}} \sum_{j=1}^n \left(\|R_j\| \left\| \frac{1}{z - \lambda_j} - \sum_{k=1}^q \frac{\tilde{r}_{kj}}{z - \mu_k} \right\|_2 \right), \quad (49)$$

where \tilde{r}_{kj} are scalar optimization variables. The inequality holds by restricting $\tilde{R}_k = \sum_{j=1}^n \tilde{r}_{kj} R_j$.

Note that the optimization variables \tilde{r}_{kj} are independent of each other. Thus, we can minimize each term for a given j separately. By Theorem 16, for a given $j = 1, \dots, n$,

$$\begin{aligned} & \min_{\tilde{r}_{1j}, \dots, \tilde{r}_{qj}} \left\| \frac{1}{z - \lambda_j} - \sum_{k=1}^q \frac{\tilde{r}_{kj}}{z - \mu_k} \right\|_2 \\ &= \frac{1}{\sqrt{1 - |\lambda_j|^2}} \left(\prod_{k=1}^q [\lambda_j, \mu_k]_h \right). \quad (50) \end{aligned}$$

Thus, the approximation error in Lemma 15 satisfies

$$\|G_e(z)\|_2 \leq \sum_{j=1}^n \frac{\|R_j\|}{\sqrt{1 - |\lambda_j|^2}} \left(\prod_{k=1}^q [\lambda_j, \mu_k]_h \right).$$

\square

Finally, we prove the results in Theorem 8.

Proof. By the result in Lemma 15, we have that

$$\begin{aligned} & \max_{G \in \mathcal{G}} \min_{\tilde{R}_1, \dots, \tilde{R}_q} \left\| G - \sum_{k=1}^q \frac{\tilde{R}_k}{z - \mu_k} \right\|_2 \\ & \leq \left[\max_{\lambda \in \mathcal{D}} \frac{1}{\sqrt{1 - |\lambda|^2}} \left(\prod_{k=1}^q [\lambda, \mu_k]_h \right) \right] \left(\sum_{j=1}^n \|R_j\| \right) \\ & \leq \max_{\lambda \in \mathcal{D}} \left[\frac{\bar{R}}{\sqrt{1 - |\lambda|^2}} \left(\prod_{k=1}^q [\lambda, \mu_k]_h \right) \right], \quad (51) \end{aligned}$$

where $\bar{R} \geq 0$ denotes the upper bound on the modified system energy of systems in \mathcal{G} defined before Theorem 8. Moreover, by choosing

$$G^*(z) = \frac{R^*}{z - \lambda^*} \in \mathcal{G},$$

where $R^* = \begin{bmatrix} \bar{R} & 0 \\ 0 & 0 \end{bmatrix} \in \mathbb{R}^{p \times m}$ and $\lambda^* \in \arg \max_{\lambda \in \mathcal{D}} \frac{1}{\sqrt{1 - |\lambda|^2}} \left(\prod_{k=1}^q [\lambda, \mu_k]_h \right)$, the approximation error in (51) achieves the upper bound:

$$\min_{\tilde{R}_1, \dots, \tilde{R}_q} \|G^* - \tilde{G}\|_2 = \max_{\lambda \in \mathcal{D}} \frac{\bar{R}}{\sqrt{1 - |\lambda|^2}} \left(\prod_{k=1}^q [\lambda, \mu_k]_h \right),$$

where $\tilde{G}(z) = \sum_{k=1}^q \frac{\tilde{R}_k}{z - \mu_k}$. Therefore,

$$\begin{aligned} & \min_{\mu_1, \dots, \mu_q \in \mathcal{D}} \max_{\lambda \in \mathcal{D}} \min_{\tilde{R}_1, \dots, \tilde{R}_q} \|G - \tilde{G}\|_2^{1/q} \\ &= \min_{\mu_1, \dots, \mu_q \in \mathcal{D}} \max_{\lambda \in \mathcal{D}} \frac{\bar{R}^{1/q}}{(1 - |\lambda|^2)^{1/2q}} \left(\prod_{k=1}^q [\lambda, \mu_k]_h \right)^{1/q}. \quad (52) \end{aligned}$$

Moreover, one can verify that

$$\begin{aligned} & \bar{R}^{1/q} \min_{\mu_1, \dots, \mu_q \in \mathcal{D}} \max_{\lambda \in \mathcal{D}} \left(\prod_{k=1}^q [\lambda, \mu_k]_{\text{h}} \right)^{1/q} \\ & \leq \min_{\mu_1, \dots, \mu_q \in \mathcal{D}} \max_{\lambda \in \mathcal{D}} \frac{\bar{R}^{1/q}}{(1 - |\lambda|^2)^{1/2q}} \left(\prod_{k=1}^q [\lambda, \mu_k]_{\text{h}} \right)^{1/q} \\ & \leq \frac{\bar{R}^{1/q}}{(1 - \rho_\lambda^2)^{1/2q}} \min_{\mu_1, \dots, \mu_q \in \mathcal{D}} \max_{\lambda \in \mathcal{D}} \left(\prod_{k=1}^q [\lambda, \mu_k]_{\text{h}} \right)^{1/q}, \end{aligned}$$

where $\rho_\lambda = \max_{\lambda \in \mathcal{D}} |\lambda|$. By taking limits on all sides of the inequality as $q \rightarrow \infty$, and applying the definition of the hyperbolic Chebyshev constant in Definition 1, we can prove that

$$\lim_{q \rightarrow \infty} \min_{\mu_1, \dots, \mu_q \in \mathcal{D}} \max_{G \in \mathcal{G}} \min_{\check{R}_1, \dots, \check{R}_q} \left\| G - \sum_{k=1}^q \frac{\check{R}_k}{z - \mu_k} \right\|_2^{1/q} = \tau(\mathcal{D}).$$

As a result, for any $\nu_1, \dots, \nu_q \in \mathcal{D}$,

$$\begin{aligned} & \liminf_{q \rightarrow \infty} \max_{G \in \mathcal{G}} \min_{\check{R}_1, \dots, \check{R}_q} \left\| G - \sum_{k=1}^q \frac{\check{R}_k}{z - \nu_k} \right\|_2^{1/q} \\ & \geq \lim_{q \rightarrow \infty} \min_{\mu_1, \dots, \mu_q \in \mathcal{D}} \max_{G \in \mathcal{G}} \min_{\check{R}_1, \dots, \check{R}_q} \left\| G - \sum_{k=1}^q \frac{\check{R}_k}{z - \mu_k} \right\|_2^{1/q} \\ & = \tau(\mathcal{D}). \end{aligned}$$

The second statement in Theorem 8 can be proved by combining Theorem 7 with (52). \square

APPENDIX III

CONFORMAL MAPPING OF REAL INTERVALS

When the region of poles \mathcal{D} is a closed real interval $\mathcal{D} = [-\rho, \rho]$, $\rho < 1$, the conformal mapping $g(z)$ that maps the region $\mathbb{D} \setminus \mathcal{D}$ to the annulus $\{w : \tau(\mathcal{D}) < w < 1\}$ can be computed explicitly, where $\tau(\mathcal{D})$ denotes the hyperbolic Chebyshev constant of the closed interval \mathcal{D} .

Theorem 17 (Conformal mapping from a real interval to an annulus). *The real interval $[-\rho, \rho]$ can be conformally mapped to the annulus $\{w : \tau(\mathcal{D}) < w < 1\}$ by the composition of the following conformal mappings:*

- **Mobius transform:**

$$m(z) = \frac{z + \rho}{1 + \rho z}. \quad (53)$$

- **Schwarz-Christoffel mapping:**

$$s(z) = \int_0^{\sqrt{\frac{z}{\tilde{\rho}}}} \frac{1}{\sqrt{(1-w^2)(1-\tilde{\rho}^2 w^2)}} dw, \quad (54)$$

where $\tilde{\rho} = \frac{2\rho}{1+\rho^2}$.

- **Translation and exponential transformations:**

$$\begin{aligned} t(z) &= -iz + 0.5iK(\sqrt{1-\tilde{\rho}^2}) + K(\tilde{\rho}), \\ \epsilon(z) &= \exp\left(\frac{\pi z}{K(\tilde{\rho})}\right). \end{aligned} \quad (55)$$

Proof. First, the Mobius transform $m(z)$ defined in (53) maps the region $\mathbb{D} \setminus \mathcal{D}$ to the region $\mathbb{D} \setminus [0, \frac{2\rho}{1+\rho^2}] = \mathbb{D} \setminus [0, \tilde{\rho}]$.

Then, by reflecting the region $\mathbb{D} \setminus [0, \tilde{\rho}]$ at $|z| = 1$, we obtain the quadrilateral $Q(\infty, 0, \tilde{\rho}, 1/\tilde{\rho})$ formed from the upper half-plane. According to [51], the following Schwarz-Christoffel mapping

$$\tilde{s}(z) = \frac{1}{2i\sqrt{\tilde{\rho}}} \int_0^z \frac{dw}{\sqrt{w(w-\tilde{\rho})(w-1/\tilde{\rho})}} \quad (56)$$

maps the region $\mathbb{D} \setminus [0, \tilde{\rho}]$ to the rectangle with the vertices $(0, K(\sqrt{1-\tilde{\rho}^2}), K(\sqrt{1-\tilde{\rho}^2}) - K(\tilde{\rho})i, -K(\tilde{\rho})i)$. Note that by substituting $w = \tilde{\rho}\tilde{w}^2$ in the integral, (56) becomes

$$\tilde{s}(z) = -i \int_0^{\sqrt{\frac{z}{\tilde{\rho}}}} \frac{d\tilde{w}}{\sqrt{(1-\tilde{w}^2)(1-\tilde{\rho}^2 \tilde{w}^2)}}.$$

For the simplicity of the inverse mapping, we move the coefficient $-i$ into the translation step. Thus, the transformation in (54) maps the region $\mathbb{D} \setminus [0, \tilde{\rho}]$ to the rectangle with the vertices $(0, K(\tilde{\rho}), iK(\sqrt{1-\tilde{\rho}^2}) + K(\tilde{\rho}), iK(\sqrt{1-\tilde{\rho}^2}))$.

To obtain the unique conformal mapping, we ensure $g(1) = 1$ by translating the rectangle by $t(z)$ and then applying the exponential transformation $\epsilon(z)$ defined in (55) to obtain the annulus $\{w : \tau(\mathcal{D}) < w < 1\}$.

The conformal mapping from the region $\mathbb{D} \setminus [-\rho, \rho]$ to the annulus $\{w : \tau([- \rho, \rho]) < w < 1\}$ is visualized in Fig. 7. \square

Therefore, we can find the points $\{\nu_{qk}\}_{k=1}^q$ of the real interval $[-\rho, \rho]$ by the following steps:

- Uniformly sample q points from the circle $\{z \in \mathbb{D} \mid |z| = \tau([- \rho, \rho])\}$ on the complex plane.
- Transform each point using the following mappings:
 - Inverse of *exponential transformation and translation*:

$$\epsilon^{-1}(z) = \frac{K(\tilde{\rho})}{\pi} \log(z),$$

$$t^{-1}(z) = iz + 0.5K(\sqrt{1-\tilde{\rho}^2}) - iK(\tilde{\rho}).$$

- Inverse of the Schwarz-Christoffel mapping:

$$s^{-1}(z) = \tilde{\rho} \operatorname{sn}(z, \tilde{\rho}^2)^2,$$

where $\operatorname{sn}(u, m)$ denotes the *Jacobi elliptic sine function*, which is the inverse function of the incomplete elliptic integral of the first kind.

- Inverse of the Mobius transform:

$$m^{-1}(z) = \frac{z - r}{1 - zr}.$$

On the other hand, when the region of poles \mathcal{D} is a continuum on the complex plane, the conformal mapping from the annulus $\{z : \tau(\mathcal{D}) < |z| < 1\}$ to the region $\mathbb{D} \setminus \mathcal{D}$ can also be numerically computed [39].

Fig. 7: Conformal mapping from the real interval $[-\rho, \rho]$ to the annulus $\{w : \tau([- \rho, \rho]) < w < 1\}$.

APPENDIX IV

RELATIONSHIP BETWEEN THE STATE-SPACE MODEL AND THE TRANSFER FUNCTION

This section discusses the relationship between the state-space model and the transfer function. First, consider an n -dimensional state-space model with m inputs and p outputs satisfying Assumption 1 and 3:

$$S : \begin{cases} x_{t+1} = Ax_t + Bu_t, \\ y_t = Cx_t. \end{cases} \quad (57)$$

Denote the eigenvalues of A as $\lambda_1, \dots, \lambda_n$. Since similarity transformation preserves the input-output relationship of the system, we directly assume that the system takes the diagonal canonical form and denote the state-space parameters as:

Proposition 18 (Markov parameter description and transfer function of a state-space model). *For a state-space representation along with parameters A, B, C , the corresponding transfer function is*

$$G(z) = \sum_{j=1}^n \frac{R_j}{z - \lambda_j}. \quad (58)$$

with $R_j = c_j b_j^\top$,

Moreover, given a transfer function with the decomposition $G(z) = \sum_{j=1}^{\kappa} \frac{R_j}{z - \lambda_j}$, one can find a corresponding state-space realization. Let

$$\varrho \triangleq \sum_{j=1}^{\kappa} \text{rank}(R_j).$$

Theorem 19 (State-space realization of Markov parameter description). *The transfer function*

$$G(z) = \sum_{j=1}^{\kappa} \frac{R_j}{z - \lambda_j} \quad (59)$$

can be realized by a ϱ -dimensional state-space model, where ϱ is at most $\min(p, m)\kappa$.

Proof. Equation (58) in Proposition 18 follows directly from the definition of transfer functions $G(z) = C(zI - A)^{-1}B$.

The rest of the proof is devoted to the state-space realization in Theorem 19. Let

$$\ell_j \triangleq \text{rank}(R_j), j = 1, \dots, n.$$

Then, for each $j = 1, \dots, n$, R_j can be decomposed as:

$$R_j = c_1^{(j)}(b_1^{(j)})^\top + \dots + c_{\ell_j}^{(j)}(b_{\ell_j}^{(j)})^\top, c_k^{(j)} \in \mathbb{C}^p, b_k^{(j)} \in \mathbb{C}^m,$$

where each product $c_k^{(j)}(b_k^{(j)})^\top$ and the corresponding vector $c_k^{(j)}, b_k^{(j)}$ can be computed via the Singular Value Decomposition (SVD) of R_j . Then, one can verify that the transfer

function (59) can be realized by the following ϱ -dimensional state-space model:

$$\begin{aligned} A &= \text{diag}(\underbrace{\lambda_1, \dots, \lambda_1}_{\ell_1 \text{ times}}, \dots, \underbrace{\lambda_n, \dots, \lambda_n}_{\ell_n \text{ times}}), \\ B &= \begin{bmatrix} b_1^{(1)} & \dots & b_{\ell_1}^{(1)} & \dots & b_1^{(n)} & \dots & b_{\ell_n}^{(n)} \end{bmatrix}^\top, \\ C &= \begin{bmatrix} c_1^{(1)} & \dots & c_{\ell_1}^{(1)} & \dots & c_1^{(n)} & \dots & c_{\ell_n}^{(n)} \end{bmatrix}. \end{aligned}$$

□

APPENDIX V

PROOF OF THEOREM 10 AND COROLLARY 11

We first prove Theorem 10.

Proof. First, we derive the KL divergence between the two hypotheses. If the samples $\{u_{t-1}, y_t\}_{t=1}^N$ are from the true system G , since we assume that the past inputs u_{-1}, u_{-2}, \dots are $\mathbf{0}$, using the expansion $G(z) = H_1 z^{-1} + H_2 z^{-2} + \dots$ where H_k are the Markov parameters of the system, we have that

$$y_t = \sum_{l=1}^t H_l u_{t-l} + v_t.$$

Let \mathcal{F}_N denote the σ -algebra generated by the inputs u_0, \dots, u_{N-1} . If the sample trajectories are from the true system, then

$$\begin{bmatrix} y_1^\top & y_2^\top & \dots & y_N^\top \end{bmatrix}^\top | \mathcal{F}_N \sim \mathcal{N}(\mathcal{G}_N \mathcal{U}_N, I_N \otimes \mathcal{R}), \quad (60)$$

where

$$\mathcal{G}_N = \begin{bmatrix} H_1 & 0 & \dots & 0 \\ H_2 & H_1 & \dots & 0 \\ \vdots & \vdots & \ddots & \vdots \\ H_N & H_{N-1} & \dots & H_1 \end{bmatrix}, \mathcal{U}_N = \begin{bmatrix} u_0 \\ u_1 \\ \vdots \\ u_{N-1} \end{bmatrix}.$$

On the other hand, if the samples are from the surrogate system \tilde{G} , then

$$\begin{bmatrix} y_1^\top & y_2^\top & \dots & y_N^\top \end{bmatrix}^\top | \mathcal{F}_N \sim \mathcal{N}(\tilde{\mathcal{G}}_N \mathcal{U}_N, I_N \otimes \mathcal{R}), \quad (61)$$

where $\tilde{\mathcal{G}}_N$ is similarly defined as \mathcal{G}_N , but is composed of $\tilde{H}_1, \dots, \tilde{H}_N$ instead.

Let

$$L_N = \frac{f_G(y_1, \dots, y_N, u_0, \dots, u_{N-1})}{f_{\tilde{G}}(y_1, \dots, y_N, u_0, \dots, u_{N-1})},$$

where f_G denotes the probability density function of $\{y_t, u_{t-1}\}_{t=1}^N$ if the samples are from the true system G , and

the notation $f_{\tilde{G}}$ is similarly defined. Then, the KL divergence between the two hypotheses in (36) can be computed as:

$$\begin{aligned} D_{\text{KL}}(\mathbb{P}_0 \parallel \mathbb{P}_1) &= D_{\text{KL}}(\mathbb{P}_1 \parallel \mathbb{P}_0) = \mathbb{E}(L_N) = \mathbb{E}[\mathbb{E}(L_N | \mathcal{F}_N)] \\ &= \frac{1}{2} \mathbb{E}[(\Delta \mathcal{G}_N \mathcal{U}_N)^\top (I_N \otimes \mathcal{R}^{-1}) \Delta \mathcal{G}_N \mathcal{U}_N], \end{aligned} \quad (62)$$

where $\Delta \mathcal{G}_N = \mathcal{G}_N - \tilde{\mathcal{G}}_N$. Since $I_N \otimes \mathcal{R}^{-1} \preceq I_{Np} \otimes \|\mathcal{R}^{-1}\|$, we can further bound the KL divergence as:

$$\begin{aligned} D_{\text{KL}}(\mathbb{P}_0 \parallel \mathbb{P}_1) &\leq \frac{\|\mathcal{R}^{-1}\|}{2} \text{tr}(\Delta \mathcal{G}_N \mathbb{E}(\mathcal{U}_N \mathcal{U}_N^\top) \Delta \mathcal{G}_N^\top) \\ &= \frac{\|\mathcal{R}^{-1}\| \text{ess sup}_\omega \|\Phi_u(\omega)\|}{2} \text{tr}(\Delta \mathcal{G}_N \Delta \mathcal{G}_N^\top) \\ &\leq \frac{\|\mathcal{R}^{-1}\| \text{ess sup}_\omega \|\Phi_u(\omega)\|}{2} \left(\sum_{t=1}^N \|H_t - \tilde{H}_t\|^2 \right) N \quad (63) \\ &\leq \frac{\|\mathcal{R}^{-1}\| \text{ess sup}_\omega \|\Phi_u(\omega)\|}{2} \|G - \tilde{G}\|^2 N \\ &\leq \frac{\bar{R}^2 \|\mathcal{R}^{-1}\| \text{ess sup}_\omega \|\Phi_u(\omega)\|}{2(1 - \rho_\lambda^2)} \tau_n(\mathcal{D})^{2n} N, \end{aligned}$$

where the last step leverages the result in Proposition 15 and the definition of the finite hyperbolic Chebyshev constant. Therefore, to ensure that the KL divergence is no smaller than δ , the sample complexity N should satisfy

$$N \geq \frac{2\delta(1 - \rho_\lambda^2)}{\bar{R}^2 \|\mathcal{R}^{-1}\| \text{ess sup}_\omega \|\Phi_u(\omega)\|} \tau_n(\mathcal{D})^{-2n}.$$

□

Next, we focus on Corollary 11. By Theorem 10, a system $\tilde{G}(z)$ with \underline{n} distinct poles can be constructed using the method in Section VI, such that the number of samples required to distinguish the true system $G(z)$ from the surrogate system $\tilde{G}(z)$ satisfies

$$N \geq \frac{2\delta(1 - \rho_\lambda^2)}{\bar{R}^2 \|\mathcal{R}^{-1}\| \text{ess sup}_\omega \|\Phi_u(\omega)\|} \tau_n(\mathcal{D})^{-2\underline{n}}.$$

Using Theorem 19, the system $\tilde{G}(z)$ has a state-space realization (A, B, C) of dimension at most

$$\underline{n} \triangleq \min(p, m) \underline{n} \leq n.$$

We can extend this realization to dimension n by appending zeros:

$$\begin{aligned} \tilde{A} &= \begin{bmatrix} A & 0 \\ 0 & 0 \end{bmatrix} \in \mathbb{C}^{n \times n}, \quad \tilde{B} = \begin{bmatrix} B \\ 0 \end{bmatrix} \in \mathbb{C}^{n \times m}, \\ \tilde{C} &= [\tilde{C} \quad 0] \in \mathbb{C}^{p \times n}. \end{aligned}$$

Thus, the system $(\tilde{A}, \tilde{B}, \tilde{C})$ is an n -dimensional system that satisfies Corollary 11.

Jiayun Li received her Bachelor of Engineering degree from Department of Automation, Tsinghua University in 2022. She is currently a Ph.D. candidate in the Department of Automation, Tsinghua University. Her

research interests include system identification, learning-based control, with applications in robotics.

Yiwen Lu received his Bachelor of Engineering degree from Department of Automation, Tsinghua University in 2020. He is currently a Ph.D. candidate in Department of Automation, Tsinghua University. His research interests include adaptive and learning-based control, with applications in robotics.

Yilin Mo is an Associate Professor in the Department of Automation, Tsinghua University. He received his Ph.D. in Electrical and Computer Engineering from Carnegie Mellon University in 2012 and his Bachelor of Engineering degree from Department of Automation, Tsinghua University in 2007. Prior to his current position, he was a postdoctoral scholar at Carnegie Mellon University in 2013 and California Institute of Technology from 2013 to 2015. He held an assistant professor position in the School of Electrical and Electronic Engineering at Nanyang Technological University from 2015 to 2018. His research interests include secure control systems and networked control systems, with applications in sensor networks and power grids.

Jie Chen (S'87–M'89–SM'98–F'07) received the B.S. degree in aerospace engineering from Northwestern Polytechnic University, Xi'an, China, in 1982, the M.S.E. degree in electrical engineering, the M.A. degree in mathematics, and the Ph.D. degree in electrical engineering all from the University of Michigan, Ann Arbor, MI, USA, in 1985, 1987, and 1990, respectively.

From 1994 to 2014, he was a Professor with the University of California, Riverside, CA, USA, and was a Professor and a Chair with the Department of Electrical Engineering from 2001 to 2006. Presently, he is a Chair Professor with the Department of Electrical Engineering, City University of Hong Kong, Hong Kong. His research interests include linear multi-variable systems theory, system identification, robust control, optimization, time-delay systems, networked control, and multi-agent systems. Dr. Chen is a Fellow of IEEE, AAAS, IFAC, SIAM, and an IEEE Distinguished Lecturer.
