(Dated: December 30, 2025)

We show that nonequilibrium spin injection into a superconductor can generate an anomalous supercurrent or induce a phase gradient, even for spin voltages below the superconducting gap. Our mechanism does not require breaking time-reversal symmetry in the effective superconducting Hamiltonian, but instead relies on nonequilibrium spin injection. We further demonstrate that superconductivity enhances spin injection due to the large quasiparticle density of states near the pairing gap, an effect that persists well below the gap. This contrasts with earlier works predicting the absence of spin injection at zero temperature and small spin voltages. Our results provide a natural explanation for long-standing experimental observations of spin injection in superconductors and predict novel effects arising from spin–charge coupling, including the electrical control of anomalous phase gradients in superconducting systems with spin–orbit coupling. These effects are broadly testable in a variety of materials and hybrid superconducting structures.

Recent research on quantum materials exhibiting superconductivity and spin–orbit coupling, as well as on superconductor–heavy-metal hybrids, has driven growing interest in non-reciprocal transport effects in superconducting systems.^{1–5} These effects may arise in different materials and structures in which both time-reversal and inversion symmetries are broken. Of particular interest are non-reciprocal effects in superconductors with intrinsic spin–orbit coupling. In this case, the resulting non-reciprocity is closely connected to the superconducting spin-galvanic effect (SGE), namely the conversion of an equilibrium spin polarization—originating from the response of the superconducting condensate to an external magnetic field—into a charge current. The SGE takes place in gyrotropic materials or structures, *i.e.*, those that allow for the existence of a second-rank pseudotensor^{3,6,7}. Most studies on superconducting SGE have so far focused on supercurrents, *i.e.*, on equilibrium properties, where time-reversal symmetry is broken either by an external dc magnetic field or by intrinsic exchange fields, such as those produced by a ferromagnet.

In this work, we focus on another situation that is also fundamental for realistic experiments: the injection of a non-equilibrium spin density into a superconductor with spin–orbit coupling and its conversion into a voltage drop or a charge current. The electrical injection of spin into superconductors is a long-standing research topic that probably started with the experiments by Tedrow and Meservey^{8,9}, in which the tunneling conductance of ferromagnet-insulator-superconductor (FIS) junctions was used to determine the spin polarization of the F electrodes, and the theoretical work by Aronov¹⁰. The basic assumption of the model, sufficient to extract the polarization of the F layers, is that the spectrum of the superconductor remains unaltered. This assumption has propagated throughout the literature since then^{11–20}.

While this assumption agrees well with experiments on non-local transport over length scales much larger than the superconducting coherence length, especially in spin-split superconductors^{17,19,21}, it fails to describe non-local effects over distances of the order of the superconducting coherence length. As an example, in Ref.¹⁴ spin is injected from a ferromagnetic injector and the non-local resistance is measured at a ferromagnetic detector some distance away. An unmodified BCS spectrum predicts an unbounded increase of the non-local resistance in the superconducting state as $T \rightarrow 0$ ¹², whereas the experiment clearly shows saturation at low temperatures. Using the kinetic theory for superconductors, we show that such a finite non-local spin signal occurs due to inevitable renormalization of the spectrum of the superconductor at the injection region, even in the absence of any inelastic relaxation processes. Our theory also naturally explains the change in the effective spin-diffusion length observed in Refs.^{14,22–24}. Specifically, we show that the spin penetration length is set by the minimum of the normal state spin relaxation length l_S and the superconducting coherence length $\xi_0 = \sqrt{D/2\Delta}$. For the injector spin voltage V_S well below the superconducting gap Δ , the injected spin density grows linearly with V_S , and for $V_S \lesssim \Delta$ the spin density injected into the superconductor is larger than in the normal state, resulting in an excess spin for $V_S > \Delta$.

We then examine how the injected spin gives rise to an electrical signal. In a superconductor with spin–orbit coupling, the injected spin naturally couples to charge transport, and can be converted into a measurable electrical response via the SGE. This manifests in different forms, as a voltage, an anomalous phase, or a current, depending on the measurement setup and on the spin voltage at the injector. Here we outline our main results.

In the open circuit setup shown in Fig. 1(c),

non-equilibrium spin injection into the superconductor through the middle normal-metal finger N induces a charge imbalance when $V_S > \Delta$. Once generated, the charge imbalance relaxes away from the contact over the characteristic charge-imbalance length $\Lambda^{*,25,26}$. As a result, a finite voltage is detected between two normal probes, 1 and 2 in Fig. 1(c), located at distances shorter than Λ^* . If one probe is placed at a distance much larger than Λ^* , the voltage difference between this probe and probes 1 or 2 acquires the opposite sign. In this open-circuit configuration, no net charge current flows through the superconductor; nevertheless, a finite phase difference develops between the two ends of the wire. When the length of the superconducting wire exceeds Λ^* , the phase difference between the ends of the S wire becomes independent of the wire length. In this sense, spin injection realizes a “phase battery”²⁷: a superconducting element that generates a persistent current when embedded in a superconducting loop, as illustrated in Fig. 1(d). The anomalous phase implies a superconducting diode effect in the nonlinear regime³. Specifically, the superconductor in Fig. 1(a) exhibits direction-dependent critical currents when a nonequilibrium spin polarization is induced. Unlike previous proposals, this mechanism does not require time-reversal symmetry breaking in the Hamiltonian but arises from the nonequilibrium spin population. In the superconducting state, the loop geometry, Fig. 1(d), has a richer phenomenology than in the normal state²⁸. If the injection spin $V_S < \Delta$, then a non-dissipative current, supercurrent, flows along the loop. In contrast, if $V_S > \Delta$, a conversion of a quasiparticle (dissipative) charge current into a pure supercurrent takes place at distances of the order of Λ^* . Thus, when the voltage is measured between the two probes located within a distance smaller than Λ^* from the injector, upper two probes in Fig. 1(d), a finite voltage will be measured. However, measuring the voltage between probes far from the injector (lower contacts in Fig. 1(d)) yields zero voltage. In the remainder of the article, we present the theoretical framework underlying these effects and provide quantitative predictions for the proposed experimental configurations. Technical details are given in the Supplementary Material (SI)²⁹.

Spin injection revisited. Here we show that it is possible to inject spin into a superconductor even at spin voltages much smaller than the gap. The reason is that the density of states (DoS) of a superconductor is, strictly speaking, never exactly zero at $\omega < \Delta$. This is, of course, not surprising in real superconductors, where inelastic processes, either intrinsic or due to the electromagnetic environment, lead to an effective finite Dynes parameter η ^{30,31}, making the in-gap DoS proportional to η . However, even for an ideal BCS superconductor with $\eta = 0$, as assumed in previous works^{12,20,21,32}, the very presence of the normal injector leads to a renormalization of the superconducting DoS in the vicinity of the contact. The induced in-gap DoS N_ω in the tunnel limit, is of the order of $\tilde{\lambda}_\omega = \frac{\lambda \xi_\omega}{D}$, where $\lambda = 1/(2e^2 R_b N_F)$, R_b is the resis-

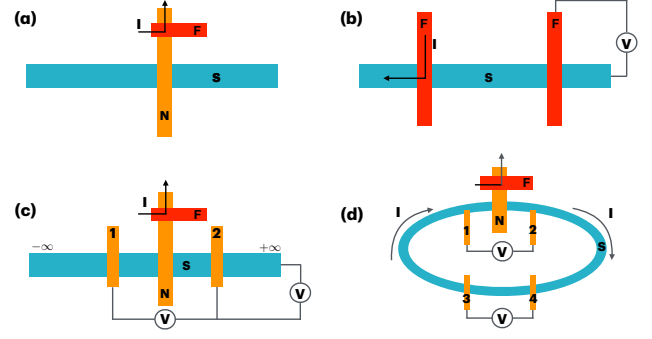

FIG. 1: (a) Schematic of the system under investigation: A normal metal (N) layer sits atop a superconductor. A spin polarized current is injected from a ferromagnetic lead (F). This results in spin accumulations within the normal metal layer, which diffuses toward the region of the metal that lies above the superconductor (S). (b)

tance of the N/S interface per unit area, ξ_ω the energy dependent superconducting coherent length, and N_F is the normal DoS at the Fermi level.

To demonstrate this, we consider the setup shown in Fig. 1(a), consisting of a quasi-one-dimensional superconducting wire (S) attached to a normal-metal injector at $x = 0$. To disentangle spin and charge transport, the electrical spin injection from a ferromagnet F is performed in the N metal, away from the N/S interface. The non-equilibrium spin injected in N diffuses toward the interface and is described by an effective spin voltage V_S ¹³. The properties of the superconductor possessing SGE are described using the Usadel equation in the Keldysh formalism^{7,33}:

$$-D\partial_x(\tilde{g}\partial_x\tilde{g}) + \partial_x\mathcal{J}_x^{sg} + [-i\omega\tau_3 + \Delta\tau_1, \tilde{g}] + \frac{1}{8\tau_s}[\sigma\tilde{g}\sigma, \tilde{g}] + \mathcal{T}^{sg} = -\lambda\delta(x)[\tilde{g}_{\text{inj}}, \tilde{g}]. \quad (1)$$

Here, \tilde{g} denotes the quasiclassical Green’s function (GF) matrix in the combined Keldysh–Nambu–spin space, σ_j and τ_j are the Pauli matrices acting in spin and Nambu space, respectively, while τ_s is the spin-relaxation time, which we assume to originate from spin-orbit scattering. Matrix current \mathcal{J}_k^{sg} and torque \mathcal{T}^{sg} are proportional to the SGE pseudotensor γ , and describe the direct and inverse SGE, respectively⁷. Their exact form is given in Eq. (A2)–(A3) of SI²⁹. The right-hand side in Eq. (1) models a local normal injector characterized by the GF \tilde{g}_{inj} with components, $g_{\text{inj}}^R = -g_{\text{inj}}^A = \tau_3$ and $g_{\text{inj}}^K = 2\tau_3 f_{\text{inj}}$, where

$$f_{\text{inj}} = \tanh[(\omega + \sigma_y V_S)/2T] = n_L + \sigma_y n_T, \quad (2)$$

is the distribution function of the normal electrode with the applied spin bias V_S .

Assuming a small γ , we solve the problem in two steps. First, we set $\gamma = 0$ and solve the spin-injection problem. Then, the SGE is analyzed perturbatively in γ .

From Eq. (1) it follows that the retarded and advanced components contain only singlet terms, $g^{R(A)}$, being proportional to the identity matrix in spin space. In contrast, the Keldysh component acquires both singlet and triplet contributions, $g^K = g_s^K + \sigma_y g_t^K$. It is customary^{13,20,34} to use the parametrization $g_t^K = (g^R - g^A) F_t \sigma_y$. Here F_t is the triplet distribution function which satisfies the following kinetic equation obtained from Eq. (1) (see section B 2 in SI):

$$-D\partial_x[d_\omega(x)\partial_x F_t] + \frac{d_\omega(x)}{\tau_s} F_t = 2\lambda\delta(x)N_\omega(0)(n_T - F_t) \quad (3)$$

where $N_\omega(x) = \text{tr}\tau_3(g^R(x) - g^A(x))/4$ is the density of states, and $d_\omega(x) = \text{tr}(1 - g^R(x)g^A(x))/4$, is a spectral function renormalizing the diffusion coefficient and the spin scattering rate. In the normal state, $g^R = -g^A = \tau_3$, and the solution of Eq. (3) takes the form:

$$F_t^N(\omega, x) = \frac{R_s/2}{R_b + R_s/2} e^{-\frac{|x|}{l_s}} n_T(\omega), \quad (4)$$

where $R_s = \rho_D l_s = l_s/(N_F D)$ is the spin resistance per unit area. As expected, the spin injected depends on the ratio between the barrier and spin resistances, and decays exponentially away from the injector on the spin diffusion length scale $l_s = \sqrt{D\tau_s}$.

In the superconducting state, assuming the tunneling limit, $R_b \gg R_s$, the spectral functions $N_\omega(x)$ and $d_\omega(x)$ can be approximated by their values at the injector, $x = 0$, multiplied by $\exp(-\tilde{\kappa}_\omega|x|)$ and $\exp(-2\tilde{\kappa}_\omega|x|)$, respectively, where $\tilde{\kappa}_\omega = \Theta(\Delta^2 - \omega^2)[1 - (\omega/\Delta)^2]^{1/4}/\xi_0$. The corresponding solution to Eq. (3) reads (SI, Sec. B 2):

$$F_t(\omega, x) = \frac{\lambda N_\omega(0) n_T(\omega)}{D d_\omega(0) \kappa_t(\omega) + \lambda N_\omega(0)} e^{-\kappa_t(\omega)|x|}, \quad (5)$$

where $\kappa_t = \sqrt{\tilde{\kappa}_\omega^2 + \kappa_s^2} - \tilde{\kappa}_\omega$ and $\kappa_s = 1/l_s$. This expression smoothly interpolates between different known limits. In particular, in the normal state, Eq. (5) is recovered after setting $N_\omega = d_\omega = 1$, and $\kappa_t = \kappa_s$.

Finally, the spectral spin density is obtained from $S_\omega(x) = \frac{1}{4} \text{tr} \{ \tau_3 g_t^K(\omega) \}$:

$$S_\omega(x) = \frac{\lambda N_\omega^2(0) n_T(\omega)}{D d_\omega(0) \kappa_t(\omega) + \lambda N_\omega(0)} e^{-\sqrt{\tilde{\kappa}_\omega^2 + \kappa_s^2}|x|} \quad (6)$$

This is an important result of the first part. It expresses the non-equilibrium spin density in terms of the spectral functions evaluated at the injection point, $x = 0$. These can be found by solving the algebraic equation, Eq. (B26) in the SI. The spectral spin density at $x = 0$ is shown in Fig. 2a. It is clearly non-zero below the gap. In the limit $l_s \ll \xi_0$, the zero-energy spin density coincides with its normal-state value. Increasing l_s the subgap spin density decreases but remains finite and $\propto \lambda$ as in the normal state. This remarkable result stems from the fact that even for an ideal BCS superconductor with zero Dynes parameter, the subgap spectral functions remain finite,

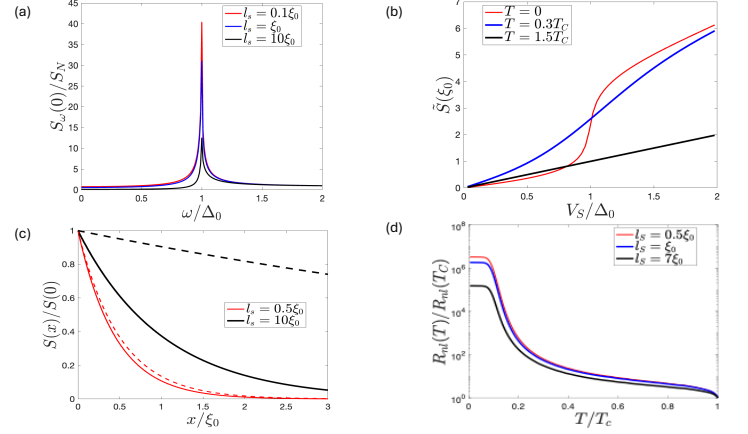

FIG. 2: (a) Spectral spin at the injector point, $x = 0$ for different values of l_s , $T = 0$, and $\tilde{\lambda} = 0.1$. (b) Dependence of the spin density at $x = \xi_0$ on the spin voltage for different temperatures, $\tilde{\lambda} = 0.05$, and $l_s = \xi_0$. (c) Spatial dependency of the injected spin density in the normal state (dashed lines) and superconducting state (solid lines) for two different values of l_s , $\tilde{\lambda} = 0.05$, $T = 0$, and $V_s = 0.5\Delta_0$. (d) Temperature dependence of the non-local resistance measured in the setup of Fig. 1(b) for different values of l_s , and $\tilde{\lambda} = 10^{-3}$. The detector is situated at a distance $2\xi_0$ from the injector.

with $N_\omega(0) \propto \lambda$ and $d_\omega(0) \propto \lambda^2$. When the energy approaches Δ , the spectral spin strongly increases, having a sharp maximum at $\omega = \Delta$. This behavior contrasts with the assumptions made in previous works^{12–14}, and as we will see has consequences in interpreting real data.

The spin density is obtained as $S(x) = \frac{N_F}{2} \int d\omega S_\omega(x)$. In Fig. 2b we show $S(\xi_0)$, for $l_s = \xi_0$, as a function of the spin voltage. Remarkably, the maximum in the spectral spin around Δ translates to an excess spin over the normal state for spin voltages exceeding the gap. In Fig. 2c we show the spatial dependence of $S(x)$ at low temperatures (solid lines) and in the normal state (dashed lines). According to Eq. (6), the characteristic spin-diffusion length in the superconducting state is determined by the minimum of l_s and the superconducting coherence length ξ_0 . In the case $l_s > \xi_0$, as in aluminum, the spin signal decays faster in the superconducting state, as indeed observed in Refs.^{14,22}. In fact, the ratio of spin diffusion lengths at $T = 0$ and $T > T_c$ gives ξ_0/l_s , which using the values for Δ , D , and l_s of that reference gives $\xi_0/l_s \approx 0.10 - 0.17$ in agreement with the experiment.

From the kinetic equations we can also compute the non-local transport signal in a non-local spin valve, such as the one sketched in Fig. 1(b), and studied in experiments^{14,18}. Details of these calculations are given in Sec C of SI. The obtained non-local resistance R_{NL} , *i.e.* the ratio between the voltage measured at the detector and the injector current I , is shown in Fig. 2d as a func-

tion of temperature. We find that, in agreement with the observations¹⁴, R_{NL} does not diverge at $T = 0$ as predicted by previous models, but instead saturates as $T \rightarrow 0$, because of the finite density of states N_0 at zero energy. The above calculations assumed a perfect BCS superconductor with vanishing Dynes parameter. The finite subgap DoS $N_0 \sim \lambda \xi_0/D = \lambda$ arises from the tunnel injector, and the zero-temperature value of $R_{NL} \sim N_0^{-2}$ is therefore proportional to $1/\tilde{\lambda}^2$. If inelastic processes dominate ($\eta > \tilde{\lambda}\Delta$), where η is the Dynes parameter, the density of states is given by $N_\omega = \text{Re}[-i(\omega + i\eta)/\sqrt{\Delta^2 - (\omega + i\eta)^2}]$, and hence $N_0 \sim \eta/\Delta$ controls the low-temperature behavior of R_{NL} . This is the case of highly resistive tunneling contacts (see Sec. B3 of SI), which we assume in the following.

Spin-charge conversion. Having established the mechanism of spin injection into a superconductor, we now study how the spin is converted into a charge signal via the SGE, for both subgap ($V_S < \Delta$) and above-gap ($V_S > \Delta$) spin biases. The triplet GF \check{g}_t , generated by the injection, determines the spin-galvanic current $\mathcal{J}_x^{sg} = \gamma \check{g}_t$, which now acts as a perturbation in the singlet channel, so that from Eq. (1) we obtain:

$$-D\check{g}_0 (\partial_x^2 \check{g}_{1s} - i\partial_x^2 \theta [\tau_3, \check{g}_0]) + [-i\omega\tau_3 + \Delta\tau_1, \check{g}_{1s}] = -\partial_x (\gamma \check{g}_t). \quad (7)$$

Here \check{g}_0 denotes the unperturbed BCS GF with finite η . We assume highly resistive tunneling contacts with $\eta/\Delta > \tilde{\lambda}$, so that \check{g}_0 is taken spatially independent. Importantly, to ensure charge conservation, we have introduced the superconducting phase θ via $\check{g} \mapsto e^{-i\tau_3\theta} \check{g} e^{i\tau_3\theta}$, which is determined from the condition $\int d\omega \text{tr} \{ \tau_2 g_s^K(\omega) \} = 0$. Details of the calculation are presented in Sec. D of SI²⁹. The charge imbalance induced by the SGE follows from g_{1s}^K as $Q_q^* = \frac{N_F}{8} \int d\omega \text{tr} g_{1s}^K(\omega)$, which determines the potential drop across the injector²⁹.

$$e\Delta\varphi = \gamma \frac{N_F \lambda \tau_s}{D} \int d\omega N_\omega n_T(\omega). \quad (8)$$

Thus, at low temperatures, and $\eta \rightarrow 0$, a finite voltage drop appears only if $V_S > \Delta$. In this case, a finite voltage difference $2V_0$ between probes 1 and 2 in Fig. 1 will be measured, provided that the probes are located at distances smaller than the charge-imbalance length Λ_{Q^*} . Measuring the voltage between probe 2 and another probe situated at a distance much larger than Λ_{Q^*} yields V_0 , whereas performing the same measurement on the opposite side gives $-V_0$.

The appearance of a charge imbalance in the superconductor is not the only consequence of spin injection. A phase gradient is also always generated²⁹. We distinguish two experimentally relevant situations. Consider first a superconductor with open boundaries, Fig1(c). In this case, no current flows, but a phase gradient is generated to compensate for the SG anomalous current. The phase difference $\delta\theta$ between the ends of the wire

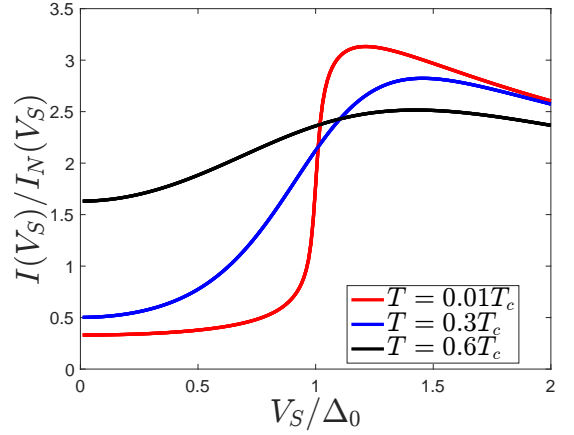

FIG. 3: The spin voltage dependence of the ratio between the current induced in the superconducting loop of Fig. 1(d) and its value in the normal state for $l_S = L = \xi_0$, and $\eta = 0.01\Delta_0$.

is found by integrating the continuity equations (see SI, Sec. D2) and is given by $\delta\theta = \gamma \bar{S}/K_s$, where \bar{S} is the total, space integrated, spin induced in the S wire, and $K_s = 2\pi\sigma_0\Delta \tanh(\Delta/2T)$. Thus, the finite wire acts as a *phase battery*, a circuit element that develops a finite phase difference between its ends. When embedded in a superconducting loop, it drives a circulating current.

This brings us to the second setup, a superconducting loop, shown in Fig. 1(d). The SGE induces a circulating current given by²⁹ $I = \gamma \bar{S}/L$, where L is the loop length. This result is identical to that of the normal state. However, in the superconducting state, for large enough values of V_S , \bar{S} is larger as in the normal state and so the circulating current. The ratio of the currents in the superconducting and normal state as a function of V_S is shown in Fig. 3. If the spin voltage V_S is smaller than Δ , the current in the loop is a pure supercurrent. In this case, both pairs of probes in Fig. 1d will measure zero voltage. In contrast, for $V_S > \Delta$, probes located at distances shorter than Λ_{Q^*} , probes 1 and 2 in Fig. 1(d), detect a finite voltage, signaling the presence of a dissipative quasiparticle current. At larger distances from the injector, this current is converted into a pure supercurrent. Consequently, probes 3 and 4 in Fig. 1(d), which are placed far from the injector, measure zero voltage, indicating purely superconducting transport. In principle, the circulating current could also be detected inductively by a second superconducting loop.

Conclusion We have presented a complete theory of the spin-galvanic effect in superconductors induced by a non-equilibrium spin. To this end, we revised the theory of spin injection, showing that even for spin voltages below the superconducting gap a finite spin can be injected. In the presence of intrinsic spin-orbit coupling, this spin generates a charge signal via the SGE. Specifically, for $V_S < \Delta$, a phase gradient develops, either as a phase drop across the superconductor in an open circuit or as a

circulating supercurrent in a loop. For $V_S > \Delta$, a charge imbalance appears, producing a voltage drop across the injector if probes are within the charge-imbalance relaxation length. Our predictions can be tested in standard multiterminal setups used in spintronics, such as nonlocal spin valves^{14,18,35} and loop geometries²⁸.

Appendix A: Usadel equation for a superconductor with spin-orbit coupling

The complete Usadel equation for a superconductor with intrinsic spin-orbit coupling reads⁷:

$$-D\partial_k(\check{g}\partial_k\check{g}) + \partial_k\mathcal{J}_k^{sg} + [-i\omega\tau_3 + \Delta\tau_1 + \check{\Sigma}, \check{g}] + \frac{1}{8\tau_s}[\check{\sigma}\check{g}\check{\sigma}, \check{g}] + \mathcal{T}^{sg} = 0. \quad (\text{A1})$$

Here τ_s is the spin diffusion time, D the diffusion coefficient, ω real frequency, and Δ , the superconducting order parameter. The SGE shows up in the matrix current, \mathcal{J}_k^{sg} , which transform the triplet GF into a singlet current

$$\mathcal{J}_k^{sg} = \frac{i}{16}\epsilon_{ijl}\gamma_{lk}\{[\check{g}, \sigma_i], \sigma_j + \check{g}\sigma_j\check{g}\} \mapsto \gamma_{jk}\check{g}_{t,j}, \quad (\text{A2})$$

where γ is the SGE pseudotensor, and the SGE matrix torque, \mathcal{T}^{sg} , transforms a singlet current into spin torque,

$$\mathcal{T}^{sg} = \frac{i}{8}\epsilon_{ijl}\gamma_{lk}\{[\partial_k\check{g}, \check{g}\sigma_i\check{g}], \sigma_j\} \quad (\text{A3})$$

The Usadel equation is complemented by the normalization condition $\check{g}^2 = 1$ and appropriate boundary conditions. We consider a quasi-one-dimensional superconducting wire (S), shown in Fig. 1(a), in contact with a normal-metal injector (N) on top. The S/N interface is described by the Kupriyanov–Lukichev boundary condition³⁶

$$n_k \check{g} \partial_k \check{g} = \lambda(x) [\check{g}_{\text{inj}}, \check{g}], \quad (\text{A4})$$

where n_k is the unit vector normal to the interface and $\lambda(x)$ is a parameter proportional to the inverse interface resistance. Since the wire is quasi-one-dimensional and the S/N interface cross section is assumed to be smaller than the spin-diffusion length, we approximate $\lambda(x)$ by a delta function, $\lambda(x) = \lambda\delta(x)$, with $\lambda = 1/(2e^2 R_b N_F)$. In this case the problem reduces to a one dimensional problem, and the boundary problem is reduced to Eq. (1) of the main text.

In what follows we focus on the spin injection from a local contact with a given spin voltage, V_S , into a quasi-1d system along x -direction. Assuming a small spin-galvanic coefficient γ , the SGE problem is solved in two steps: (i) the spin injection at $\gamma_{jk} = 0$ (section B 1, and (ii) the spin-charge conversion perturbatively in γ_{jk} (section D). In what follows, we use the $\check{\cdot}$ for denoting 8×8 matrices, Keldysh-Nambu-spin space. The $\hat{\cdot}$ symbol denotes 4×4 in the Nambu-spin space, whereas g 's denote 2×2 in the Nambu space.

Appendix B: Spin injection problem: Spin-biased injector

Here we focus on the spin-injection problem neglecting first the SGE. The Usadel equation reads:

$$-D\partial_k(\check{g}\partial_k\check{g}) + [-i\omega\tau_3 + \Delta\tau_1, \check{g}] + \frac{1}{8\tau_s}[\check{\sigma}\check{g}\check{\sigma}, \check{g}] + \lambda(x) [\check{g}_{\text{inj}}, \check{g}] = 0 \quad (\text{B1})$$

where $\lambda(x)$ is a tunneling rate from the injector assumed to be localized at the origin. The normal metal injector, N finger in Fig. 1(a) in the main text, is described by following GFs:

$$g_{\text{inj}}^R = -g_{\text{inj}}^A = \tau_3, \quad (\text{B2})$$

$$\hat{g}_{\text{inj}}^K = 2\tau_3 \tanh\left(\frac{\omega + \sigma_y V_s}{2T}\right) = 2\tau_3 (n_L + \sigma_y n_T), \quad (\text{B3})$$

where V_s is an effective “spin bias”, induced, for example, by the electrical spin injection from a ferromagnet (see 1(a) in the main text).

Equations for the retarder/advanced components read

$$-D\partial_x(g^{R,A}\partial_x g^{R,A}) + [-i\omega\tau_3 + \Delta\tau_1, g^{R,A}] \pm \lambda(x) [\tau_3, g^{R,A}] = 0 \quad (\text{B4})$$

In fact, the spectral GF have only singlet (scalar) component. In contrast, the Keldysh component acquires both singlet and triplet parts,

$$\hat{g}^K = g_s^K + \sigma_y g_t^K. \quad (\text{B5})$$

The triplet part satisfies the

$$\begin{aligned} -D\partial_x (g^R\partial_x g_t^K + g_t^K\partial_x g^A) + [-i\omega\tau_3 + \Delta\tau_1, g_t^K] + \frac{1}{2\tau_s} (g^R g_t^K - g_t^K g^A) \\ + \lambda(x) (\tau_3 g^K + g^K \tau_3 - g^R 2\tau_3 n_T + 2\tau_3 n_T g^A) = 0 \end{aligned} \quad (\text{B6})$$

In order to obtain the injected spectral spin density, $S_\omega(x) = \frac{1}{4}\text{tr}\{\tau_3 g_t^K(\omega)\}$ we will solve Eqs. (B4-B6) in different situations. From the spectral spin one obtains the physical spin from $S = (N_F/2) \int d\omega S_\omega$.

1. Spin injection in the normal state

In the normal state $\Delta = 0$ and $g^R = -g^A = \tau_3$, which dramatically simplifies the problem. It follows from (B6) that $g_t^K = 2\tau_3 F_t$, where the distribution function satisfies the equation

$$-D\partial_x^2 F_t + \frac{1}{\tau_s} F_t = 2\lambda\delta(x)(n_T - F_t) \quad (\text{B7})$$

where I assumed that the size of the injector is much smaller than the spin diffusion length $l_s = \sqrt{D\tau_s}$, so that the local tunneling rate can be represented as $\lambda(x) = \lambda\delta(x)$, with $\lambda = 1/2e^2 R_b N_F$, and R_b is the contact (barrier) resistance per area, The solution of (B7) is:

$$F_t(\omega, x) = \frac{\lambda l_s/D}{1 + \lambda l_s/D} e^{-\frac{|x|}{l_s}} n_T(\omega) = \frac{R_s/2}{R_b + R_s/2} e^{-\frac{|x|}{l_s}} n_T(\omega). \quad (\text{B8})$$

where $R_s = l_s/\sigma_D$ is the spin resistance per area, with σ_D being the Drude conductivity $\sigma_D = e^2 N_F D$. The factor of 1/2 in Eq. (B8) signifies the fact that the parts of the wire on the opposite sides from the injector work effectively as parallel resistors. Thus, the injection in the normal metallic wire is characterized by a single dimensionless parameter,

$$\frac{\lambda l_s}{D} = \frac{\lambda N_F l_s}{N_F D} = \frac{R_s}{2R_b}$$

that is the ratio of characteristic resistances. The tunneling limit corresponds to the regime $R_b \gg R_s$. In the opposite limit of $\lambda l_s/D \gg 1$ the contact is transparent. In what follows, we focus on tunneling contacts.

2. Spin injection in ideal superconductors with vanishing Dynes parameters

We first focus on a perfect BCS superconductor without inelastic processes. This situation coincides with previous theory works^{12,13,21,32,37}. It is customary to parametrize the Keldysh GF g_t^K as²⁰,

$$g_t^K = (g^R - g^A)F_t \quad (\text{B9})$$

where $g^{R,A}$ are the solutions to (B4). By inserting the representation (B9) into Eq.(B6), and taking its trace we obtain the following exact kinetic equation for the distribution function in the SC

$$\begin{aligned} -D\partial_x (\text{tr}\{1 - g^R g^A\} \partial_x F_t) + \frac{1}{\tau_s} \text{tr}\{1 - g^R g^A\} F_t \\ = 2\lambda(x) \text{tr}\{\tau_3 (g^R - g^A)\} (n_T - F_t) \end{aligned} \quad (\text{B10})$$

It has a structure similar to Eq.(B7) in the normal state, but with renormalized kinetic coefficients,

$$D \mapsto D_\omega(x) = \frac{D}{4} \text{tr}\{1 - g^R g^A\} = \frac{D}{8} \text{tr}\{(g^R - g^A)^2\} \equiv D d_\omega(x) \quad (\text{B11})$$

$$\begin{aligned} \frac{1}{\tau_s} \mapsto \frac{1}{\tau_s(\omega, x)} = \frac{1}{4\tau_s} \text{tr}\{1 - g^R g^A\} = \frac{1}{8\tau_s} \text{tr}\{(g^R - g^A)^2\} = \frac{d_\omega(x)}{\tau_s} \\ \lambda \mapsto \lambda_\omega(x) = \frac{\lambda}{4} \text{tr}\{\tau_3 (g^R - g^A)\} = \lambda N_\omega(x) \end{aligned} \quad (\text{B12})$$

In the tunneling regime, the kinetic equation can be solved analytically, in two limiting cases.

1. In the limit of small energies $\omega \ll \Delta$ a complete analytic solution is possible because in this case the spatial dependence of the renormalized kinetic coefficients is exponential.
2. In the limit of a short spin relaxation length, when $l_s \ll \xi = \sqrt{\frac{D}{2\Delta}}$. As $d_\omega(x)$ and $N_\omega(x)$ are varying on the scale large than ξ , while the characteristic scale of eq.(B10) is l_s , we can the spatial dependence of the kinetic coefficient in (B10) and solve it the same way as in the normal metal.

In the next two subsections, we present these two cases, which will help to construct a general solution by interpolation.

a. Spin injection in the small energy limit.

In the case of small energy, and within the tunneling limit, the Usadel equation for $g^{R,A}(\omega, x)$, eq.(B4) can be solved perturbatively to the linear order in $\lambda\xi/D$. The linearized in λ equation for g^R reads

$$-Dg_0^R \partial_x^2 g_1^R + \Omega_\omega [g_0^R, g_1^R] + \lambda(x) [\tau_3, g_0^R] = 0$$

where g_0^R is the BCS GF and $\Omega_\omega = \sqrt{\Delta^2 - \omega^2}$. After multiplication with g_0^R the above equation takes the form,

$$-D\partial_x^2 g_1^R + 2\Omega_\omega g_1^R = \lambda(x) (\tau_3 - g_0^R \tau_3 g_0^R) \quad (\text{B13})$$

For the kinetic coefficients in Eqs.(B11)-(B12) we need to obtain $g^R - g^A$. The equation for this difference is obtained by subtracting from (B13) its advanced counterpart,

$$-\partial_x^2 (g^R - g^A) + \kappa_\omega^2 (g^R - g^A) = \frac{2\lambda}{D} \delta(x) \frac{2\Delta^2}{\Delta^2 - \omega^2} \tau_3 \quad (\text{B14})$$

where $\kappa_\omega = \xi_\omega^{-1} = \sqrt{\frac{2\Omega_\omega}{D}}$ is the inverse spectral coherence length. We have used the fact that below the gap $g_0^R = g_0^A = \frac{-i\omega\tau_3 + \Delta\tau_1}{\Omega_\omega}$. The solution to Eq. (B14) reads,

$$g^R - g^A = 2\tau_3 \frac{\lambda\xi_\omega}{D} \frac{\Delta^2}{\Delta^2 - \omega^2} e^{-\kappa_\omega|x|} = 2\tau_3 \tilde{\lambda}_\omega e^{-\kappa_\omega|x|} \quad (\text{B15})$$

The validity of this solution assumes the condition

$$\tilde{\lambda}_\omega = \frac{\lambda\xi_\omega}{D} \frac{\Delta^2}{\Delta^2 - \omega^2} \ll 1$$

which is definitely satisfied for low energies in the tunneling regime when $\tilde{\lambda}_\omega \approx \tilde{\lambda}_0 = \frac{\lambda\xi_0}{D}$. From eq.(B15) we immediately find the required kinetic coefficients,

$$N_\omega(x) = \frac{1}{4} \text{tr} \{ \tau_3 (g^R - g^A) \} = \tilde{\lambda}_\omega e^{-\kappa_\omega|x|} \quad (\text{B16})$$

$$d_\omega(x) = \frac{1}{8} \text{tr} \{ (g^R - g^A)^2 \} = \tilde{\lambda}_\omega^2 e^{-2\kappa_\omega|x|} \quad (\text{B17})$$

The kinetic equation (B10) then takes the following form

$$-e^{2\kappa_\omega|x|} \partial_x \left(e^{-2\kappa_\omega|x|} \partial_x F_t \right) + \kappa_s^2 F_t = \frac{2\lambda}{D\tilde{\lambda}_\omega} \delta(x) (n_T - F_t) \quad (\text{B18})$$

where $\kappa_s = \xi_s^{-1} = 1/\sqrt{D\tau_s}$. It is remarkable that the r.h.s. in (B18) is independent of the tunneling rate λ :

$$\frac{\lambda}{D\tilde{\lambda}_\omega} = \kappa_\omega \left(1 - \frac{\omega^2}{\Delta^2} \right).$$

In other words, in the parametrization Eq. (B9), the distribution function does not depend on λ . One can check by a direct substitution that the solution of (B18) is of the form

$$F_t(x) = F_t(0) e^{-(\sqrt{\kappa_\omega^2 + \kappa_s^2} - \kappa_\omega)|x|}$$

where the value of $F_t(0)$ is found from the boundary condition

$$[\partial_x F_t]_{-0}^{+0} = 2\kappa_\omega \left(1 - \frac{\omega^2}{\Delta^2}\right) [n_T - F_t(0)]$$

By resolving this condition we find the final distribution function,

$$F_t(x) = \frac{\kappa_\omega (1 - \omega^2/\Delta^2) n_T(\omega)}{\sqrt{\kappa_\omega^2 + \kappa_s^2 - \kappa_\omega \omega^2/\Delta^2}} e^{-(\sqrt{\kappa_\omega^2 + \kappa_s^2} - \kappa_\omega)|x|}. \quad (\text{B19})$$

We then obtain for the spectral spin density,

$$S_\omega(x) = F_t(\omega, x) N_\omega(x) = \frac{\lambda n_T(\omega)/D}{\sqrt{\kappa_\omega^2 + \kappa_s^2 - \kappa_\omega \omega^2/\Delta^2}} e^{-\sqrt{\kappa_\omega^2 + \kappa_s^2}|x|} \quad (\text{B20})$$

In the small energy limit this result simplifies as,

$$S_\omega(x) \approx \frac{R_s}{R_b} n_T(\omega) \frac{\kappa_s}{\sqrt{\kappa_0^2 + \kappa_s^2}} e^{-\sqrt{\kappa_0^2 + \kappa_s^2}|x|} \quad (\text{B21})$$

In the limit of short spin diffusion length $\kappa_s \gg \kappa_\omega$ the above small energy spin density in SC coincides with the spectral spin in the normal metal (*cf.* with Eq. (B8) when $R_b \gg R_s$),

$$S_\omega^N(x) \approx \frac{R_s}{R_b} n_T(\omega) e^{-\kappa_s|x|}$$

In short, even in the case of an ideal BCS superconductor with $\eta = 0$, the tunneling contact provides a finite density of states at $\omega = 0$, which leads to a finite subgap spin density, in contrast with the assumptions of previous works^{12,14,32}.

b. Spin injection in the limit of a short spin diffusion length

Now, let us assume that the spin diffusion length is short, $l_s \ll \xi_0(0)$, where $\xi_0(0) = \xi_{\omega=0}(T=0)$. In this limit, the spatial dependence of the kinetic coefficients can be neglected and in (B10) we can simply replace $d_\omega(x)$ by its value at the injector, i.e., $d_\omega(x) \mapsto d_\omega(0)$. Equation (B10) then simplifies to the form

$$-\partial_x^2 F_t + \kappa_s^2 F_t = \frac{2\lambda N_\omega(0)}{D d_\omega(0)} \delta(x) (n_T - F_t)$$

which is essentially identical to the kinetic equation in the normal metal and is solved in the same way. The solution is,

$$F_t(\omega, x) = \frac{\frac{\lambda l_s N_\omega(0)}{D d_\omega(0)}}{1 + \frac{\lambda l_s N_\omega(0)}{D d_\omega(0)}} n_T(\omega) e^{-\kappa_s|x|} \quad (\text{B22})$$

Notice that in the tunneling limit when $\lambda l_s/D = R_s/R_b \ll 1$. The functions $N_\omega(0)$ and $d_\omega(0)$ are expressed in terms of components of $g_\omega^R(x) = g_\omega(x)\tau_3 + f_\omega(x)\tau_1$ at the injector point,

$$\begin{aligned} N_\omega(0) &= \frac{1}{4} \text{tr} \{ \tau_3 (g^R(0) - g^A(0)) \} = \text{Re } g_\omega(0) \\ d_\omega(0) &= \frac{1}{8} \text{tr} \{ (g^R(0) - g^A(0))^2 \} = [\text{Re } g_\omega(0)]^2 - [\text{Im } f_\omega(0)]^2 \end{aligned}$$

Calculation of $g(0)$ and $f(0)$ can be reduced to solving an algebraic quartic equation. To derive this equation I represent the Usadel equation for $g^R(x) = g(x)\tau_3 + f(x)\tau_1$ in the following explicit form

$$-\frac{D}{2} \partial_x [g(x) \partial_x f(x) - f(x) \partial_x g(x)] - i\omega f(x) - \Delta g(x) = 0 \quad (\text{B23})$$

$$-\frac{D}{2} [g(x) \partial_x f(x) - f(x) \partial_x g(x)]_{-0}^{+0} = \lambda f(0) \quad (\text{B24})$$

Here the boundary condition (B24) represents the injection δ -function. In addition, the normalization $g^2(x) + f^2(x) = 1$ is assumed. By multiplying Eq.(B23) with $g(x)\partial_x f(x) - f(x)\partial_x g(x)$ one can represent it in a total derivative form

$$\partial_x \left(\frac{D}{4} [g(x)\partial_x f(x) - f(x)\partial_x g(x)]^2 - i\omega g(x) + \Delta f(x) \right) = 0$$

The integration of this equation from a given point x to ∞ gives the first integral of the Usadel equation:

$$\frac{D}{4} [g(x)\partial_x f(x) - f(x)\partial_x g(x)]^2 - i\omega g(x) + \Delta f(x) = \sqrt{\Delta^2 - (\omega + i0)^2} \quad (\text{B25})$$

where the r.h.s. corresponds to $[-i\omega g(x) + \Delta f(x)]_{x=\infty}$. We now evaluate eq.(B25) at $x = 0$ and substitute the boundary condition (B24) for the first term. This yields an algebraic equation,

$$\frac{\lambda^2}{4D} f^2(0) - i\omega g(0) + \Delta f(0) = \sqrt{\Delta^2 - (\omega + i0)^2}$$

which, together with the normalization condition $g^2(0) + f^2(0) = 1$, fully determines the required functions $g_\omega(0)$ and $f_\omega(0)$. It is useful to rewrite the above equation in terms of dimensionless parameters,

$$\frac{1}{2} \tilde{\lambda} f^2 - izg + f - \sqrt{1 - z^2} = 0 \quad (\text{B26})$$

where $z = \frac{\omega}{\Delta} + i0$, and $\tilde{\lambda} = \frac{\lambda}{\sqrt{2\Delta D}} = \frac{\lambda \xi_0}{D}$ is the only dimensionless parameter which controls the solution. By squaring this equation can be reduced to a closed quartic equation either for g or for f . It becomes quadratic at $z = 0$, and also possesses a relatively simple analytic solution in the gap region at $z \approx 1$ in the limit $\tilde{\lambda} \ll 1$. Specifically, assuming $\lambda \ll 1$, and solving the squared equation for g we obtain for zero energy,

$$g_0(0) \approx \tilde{\lambda}$$

which agrees with Eq.(B15). In the vicinity of the gap for $|z - 1| \ll 1$ the solution reads,

$$g(z) \approx \tilde{\lambda}^{-\frac{2}{3}} \left\{ e^{-i\frac{\pi}{6}} - \frac{2}{3} \tilde{\lambda}^{-\frac{2}{3}} e^{i\frac{\pi}{6}} \sqrt{1 - z^2} \right\}$$

Notice that since $z = \frac{\omega}{\Delta} + i0$, the square root in the above equation reads,

$$\sqrt{1 - z^2} = \sqrt{1 - z^2} \theta(1 - z^2) - i \sqrt{z^2 - 1} \theta(z^2 - 1)$$

c. Interpolation scheme smoothly connecting known limits

From the previous sections it becomes clear that (i) the tunneling contact modifies the spectral Green's functions, and (ii) these modifications decay on the scale of κ_ω , for energies inside the gap. Therefore, it looks reasonable to approximate the space dependence of spectral coefficients $d_\omega(x)$ and $N_\omega(x)$, Eqs. (B11) and (B12), by the following simple exponential functions,

$$N_\omega(x) = N_\omega(0) e^{-\tilde{\kappa}_\omega |x|} \quad (\text{B27})$$

$$d_\omega(x) = d_\omega(0) e^{-2\tilde{\kappa}_\omega |x|} \quad (\text{B28})$$

Here $N_\omega(0)$ and $d_\omega(0)$ are the exact values at the contact, and we define $\tilde{\kappa}_\omega^2 = \theta(\Delta^2 - \omega^2) 2\sqrt{\Delta^2 - \omega^2}/D$ which takes care of the fact that above the gap the density of states is well approximated by a space independent function. In fact, in the limit of small tunneling rate λ the essential relative modifications of all the spectral coefficients are in the gap region. Note that the heuristic construction of Eqs. (B27)-(B28) is inspired by the small-energy solution of Eqs. (B16)-(B17). With this assumption, the kinetic equation, Eq. (B10), takes the form structurally identical to its low energy form (B18),

$$-e^{2\tilde{\kappa}_\omega |x|} \partial_x \left(e^{-2\tilde{\kappa}_\omega |x|} \partial_x F_t \right) + \kappa_s^2 F_t = \frac{2\lambda N_\omega(0)}{D d_\omega(0)} \delta(x) (n_T - F_t) \quad (\text{B29})$$

Therefore the solution of (B29) is again of the form

$$F_t(x) = F_t(0)e^{-(\sqrt{\bar{\kappa}_\omega^2 + \kappa_s^2} - \bar{\kappa}_\omega)|x|}. \quad (\text{B30})$$

The difference is that now $F_t(0)$ is determined by a slightly modified boundary condition

$$[\partial_x F_t]_{-0}^{+0} = -\frac{2\lambda N_\omega(0)}{Dd_\omega(0)}[n_T - F_t(0)]$$

The final solution for the distribution function then takes the form

$$F_t(x) = \frac{\lambda N_\omega(0)n_T}{Dd_\omega(0)\kappa_t(\omega) + \lambda N_\omega(0)}e^{-\kappa_t(\omega)|x|} \quad (\text{B31})$$

where $\kappa_t(\omega) = \sqrt{\bar{\kappa}_\omega^2 + \kappa_s^2} - \bar{\kappa}_\omega$. This result for the distribution function, interpolates smoothly between all previous limiting cases. Namely,

- the short l_s limit of Eq. (B22), which corresponds to $\kappa_s \gg \kappa_\omega$;
- the low energy limit of Eq. (B19);
- the normal state limit in which $\Delta = 0$ leading to $N_\omega = d_\omega = 1$ and $\kappa_t(\omega) = \kappa_s$. In this limit we recover Eq. (B8)

The corresponding spectral spin is therefore

$$S_\omega(x) = F_t(x)N_\omega(x) = \frac{\lambda N_\omega^2(0)n_T}{Dd_\omega(0)\kappa_t(\omega) + \lambda N_\omega(0)}e^{-\sqrt{\bar{\kappa}_\omega^2 + \kappa_s^2}|x|} \quad (\text{B32})$$

This expression for the spin also recovers all above limits except for the case of “transparent contact” because for $\lambda \rightarrow \infty$ the assumption Eq. (B27) is not valid (in this case gap closes at the contact point so that $N_\omega(0) = 1$).

In the main text, we focus on tunneling contacts. To create Fig. 2 (a-c) we use Eq. (B32) by solving Eq. (B26) to determine the spectral functions $d_\omega(0)$ and $N_\omega(0)$ at the injection point.

3. Spin injection in a superconductor with a finite Dynes parameter: tunneling limit

In the previous sections, we have assumed an ideal BCS superconductor, *i.e.*, a superconductor with an exactly zero density of states below the gap. However, real superconductors do not exhibit a perfect gap, either due to intrinsic inelastic processes or extrinsic ones, such as coupling to the electromagnetic environment³⁰. Such effects may be qualitatively described by a single parameter η , the so-called Dynes parameter. In this section we compute the spin injected in a superconductor with a finite η .

We focus on the tunneling limit and calculate again the Keldysh triplet component. The retarded and advance GF's are now homogeneous in space To the linear order in the tunneling rate the equation has the simple form:

$$-D\partial_x^2 g_t^K + (\Omega_R + \Omega_A)g_t^K + \frac{1}{\tau_s}g_t^K = 2\lambda\delta(x)(\tau_3 - g_0^R\tau_3g_0^A)n_T \quad (\text{B33})$$

where $\Omega_{R,A} = \sqrt{\Delta^2 - (\omega \pm i\eta)^2}$ and the unperturbed GFs are defined as,

$$g_0^{R,A} = \frac{-i(\omega \pm i\eta)\tau_3 + \Delta\tau_1}{\Omega_{R,A}}. \quad (\text{B34})$$

The triplet component of g^K can be obtained straightforwardly:

$$g_t^K = \frac{\lambda e^{-|x|\sqrt{\bar{\kappa}_\omega^2 + \kappa_s^2}}}{D\sqrt{\bar{\kappa}_\omega^2 + \kappa_s^2}}(\tau_3 - g_0^R\tau_3g_0^A)n_T \quad (\text{B35})$$

. The spectral spin density, $S_\omega(x) = \frac{1}{4}\text{tr}\{\tau_3 g_t^K(\omega)\}$, is then given by:

$$S_\omega(x) = \frac{\lambda N_\omega^2 n_T(\omega)}{Dd_\omega\sqrt{\bar{\kappa}_\omega^2 + \kappa_s^2}}e^{-|x|\sqrt{\bar{\kappa}_\omega^2 + \kappa_s^2}} \quad (\text{B36})$$

where we have used the following identity for GFs,

$$g_0^R - g_0^A = \frac{2\eta}{\Omega_R + \Omega_A} (\tau_3 - g_0^R \tau_3 g_0^A)$$

By computing the spin density $S(x)$ from the expression of Eq. (B36), one can see that it qualitatively behaves like that of an ideal BCS superconductor (Fig. 1b in the main text). First, it does not vanishes for $V_S < \Delta$, and for $V_S \sim \Delta$, the spin density in the superconducting state is much larger than in the normal state.

4. Electric detection of injected spin by a magnetic probe

In order to electrically detect the spin injected at $x = 0$, one may place a ferromagnetic probe F at a distance x_d from the injector. A sizable spin signal may appear if x_d is smaller than the characteristic decay length of the spin, determined by the minimum of l_S and x_{i0} .

We assume that the F-electrode, located at the point x_d , is polarize in the same direction as the spin injected, *i.e.* σ_y . The electrode is described by the following term in the Usadel equation,

$$\check{J}_d \delta(x - x_d) = \lambda_d [\Gamma \check{g}_d \Gamma, \check{g}] \delta(x - x_d) \quad (\text{B37})$$

where $\lambda_d = 1/2e^2 N_F R_d$, R_d is the S/F interface resistance times area, and \check{g}_d is the GF of the normal detector electrode

$$g_d^R = -g_d^A = \tau_3, \quad (\text{B38})$$

$$g_d^K = 2\tau_3 \tanh\left(\frac{\omega + \tau_3 V_d}{2T}\right) = 2\tau_3 (n_L + \tau_3 n_T) \quad (\text{B39})$$

and $\Gamma = t + \tau_3 \sigma_y u$ with $t^2 + u^2 = 1$ and $2tu = P$ is the spin filtering operator accounting for the spin polarization of the detector. For a compact characterization of the F-electrode it is natural to introduce the effective GF,

$$\check{G}_d = \Gamma \check{g}_d \Gamma \quad (\text{B40})$$

whose components are easily found to be,

$$G_d^R = -G_d^A = \tau_3 + P_d \sigma_y \quad (\text{B41})$$

$$G_d^K = 2(\tau_3 + P \sigma_y)(n_L + \tau_3 n_T) \quad (\text{B42})$$

The charge current in the detector is calculated as,

$$I_d = -\frac{\pi}{4} N_F \int \frac{d\omega}{2\pi} \text{tr} \{ \tau_3 \check{J}_d^K \} = -\frac{1}{8} N_F \lambda_d \int d\omega \text{tr} \{ \tau_3 [\check{G}_d, \check{g}(x_d)]^K \}$$

Using \check{g} generated by the spin-biased electrode we get,

$$\frac{1}{8} \text{tr} \{ \tau_3 [\check{G}_d, \check{g}]^K \} = N_\omega (P_d F_t - n_T)$$

Therefore the current in the detector reads

$$I_d = R_d^{-1} \frac{1}{2} \int d\omega [N_\omega(x_d) n_T - P_d N_\omega(x_d) F_t(x_d)] \quad (\text{B43})$$

The second term in the r.h.s. is the injected spin at location of the detector times the polarization of the detector. The condition $I_d = 0$ determines the detector voltage, which can be obtained by solving following integral equation:

$$\int d\omega N_\omega(x_d) n_T(V_d) = P_d \int S_\omega(x_d) d\omega \quad (\text{B44})$$

Appendix C: Electric spin injection from magnetic electrode

In the previous sections, we considered spin injection via a spin voltage induced in a normal (N) electrode; see Fig. 1a in the main text. However, in experiments, spin is usually injected from ferromagnetic (F) electrodes by driving a spin-polarized current^{14,18,22,35}. In this section, we analyze this situation.

1. General kinetic equations

The Usadel equation for a wire with ferromagnetic contact at $x = 0$ reads,

$$-D\nabla_x(\check{g}\nabla_x\check{g}) + [-i\omega\tau_3 + \Delta\tau_1, \check{g}] + \frac{1}{8\tau_s}[\sigma\check{g}\sigma, \check{g}] = -\lambda\delta(x) [\check{G}_F(V), \check{g}] \quad (C1)$$

where Δ is real and $\nabla_k g = \partial_k g - i[\partial_k \varphi \tau_3, g]$, which accounts for a possibility of having a supercurrent. The Green function \hat{G}_F of the normal F-electrode with polarization P along y -axis read [see Eqs. (B40)-(B42)],

$$\begin{aligned} G_F^R &= -G_F^A = \tau_3 + P\sigma_y \\ G_F^K &= 2(\tau_3 + P\sigma_y)(n_L + \tau_3 n_T) \end{aligned}$$

From Eq. (C1), $g^{R,A}$ have trivial spin structure. The equation for them is given by Eq. (B4) after replacing $\partial_k \rightarrow \nabla_k$, that is,

$$-D\nabla_x(g^R\nabla_x g^R) + [-i\omega\tau_3 + \Delta\tau_1, g^R] + \lambda\delta(x) [\tau_3, g^R] = 0 \quad (C2)$$

$$-D\nabla_x(g^A\nabla_x g^A) + [-i\omega\tau_3 + \Delta\tau_1, g^A] - \lambda\delta(x) [\tau_3, g^A] = 0 \quad (C3)$$

The Keldysh component is naturally separated into the singlet and triplet parts,

$$g^K = g_s^K + \sigma_y g_t^K$$

and can then be represented in terms of four distribution functions,

$$g_s^K = (g^R - g^A)F_s^L + (g^R\tau_3 - \tau_3 g^A)F_s^T \quad (C4)$$

$$g_t^K = (g^R - g^A)F_t^T + (g^R\tau_3 - \tau_3 g^A)F_t^L \quad (C5)$$

In previous section, where a pure spin biased injector was consider, the triplet channel generates only F_t^T and was completely decoupled from the rest. Now however, by substituting the above representation for g^K into the Keldysh component of Eq. (C1) and taking the traces with τ_3 , 1, σ_y , and $\tau_3\sigma_y$ one get four coupled equations,

$$\begin{aligned} -D\partial_x(\tilde{d}_\omega\partial_x F_s^T) - Dj_{x,\omega}\partial_x F_s^L + \frac{1}{2}\Delta\text{tr}\{\tau_1(g^R + g^A)\}F_s^T \\ = 2\lambda N_\omega\delta(x)[n_T - F_s^T - PF_t^T] \end{aligned} \quad (C6)$$

$$-D\partial_x(d_\omega\partial_x F_s^L + j_{x,\omega}F_s^T) = 2\lambda N_\omega\delta(x)[n_L - F_s^L - PF_t^L] \quad (C7)$$

$$-D\partial_x(d_\omega\partial_x F_t^T + j_{x,\omega}F_t^L) + \frac{d_\omega}{\tau_s}F_t^T = 2\lambda N_\omega\delta(x)[P(n_T - F_s^T) - F_t^T] \quad (C8)$$

$$\begin{aligned} -D\partial_x(\tilde{d}_\omega\partial_x F_t^L) - Dj_{x,\omega}\partial_x F_t^T + \frac{1}{2}\Delta\text{tr}\{\tau_1(g^R + g^A)\}F_t^L \\ + \frac{d_\omega}{\tau_s}F_t^L = 2\lambda N_\omega\delta(x)[P(n_L - F_s^L) - F_t^L] \end{aligned} \quad (C9)$$

Here the coefficients are defined as follows

$$\begin{aligned} d_\omega(x) &= \frac{1}{4}\text{tr}\{1 - g^R g^A\} \\ N_\omega(x) &= \frac{1}{4}\text{tr}\{g^R - g^A\} \\ \tilde{d}_\omega(x) &= \frac{1}{4}\text{tr}\{1 - \tau_3 g^R \tau_3 g^A\} \end{aligned} \quad (C10)$$

$$j_{x,\omega}(x) = \frac{1}{4}\text{tr}\{\tau_3(g^R\nabla_x g^R - g^A\nabla_x g^A)\} \equiv n_\omega(x)\partial_x\varphi \quad (C11)$$

$$n_\omega(x) = -\frac{i}{4}\text{tr}\{\tau_3 g^R \tau_3 g^R - \tau_3 g^A \tau_3 g^A\} \quad (C12)$$

The phase gradient in these equation is determined from the selfconsistency condition

$$\int d\omega\text{tr}\{\tau_2 g^K\} = \int d\omega\text{tr}\{\tau_2(g^R - g^A)F_s^L - i\tau_1(g^R + g^A)F_s^T\} = 0 \quad (C13)$$

which is equivalent to enforcing the charge conservation. Formally, the condition (C13) ensures that after the energy integration Eq. (C6) becomes the continuity equation. This can be seen as follows. Let us trace Eqs.(C2) and (C3) with τ_3 and subtract them from each other. The result is the following identity,

$$D\partial_x j_{x,\omega} = \frac{i}{2}\Delta \text{tr} \{ \tau_2 (g^R - g^A) \}$$

Using this identity I rewrite the selfconsistency condition in the form

$$\frac{\Delta}{2} \int d\omega \text{tr} \{ \tau_1 (g^R + g^A) F_s^T \} = -D \int d\omega F_s^L \partial_x j_{x,\omega} \quad (\text{C14})$$

This equation guaranties that after the ω -integration the l.h.s. in Eq.(C6) becomes a total divergence, and can be written as follows,

$$\partial_x J(x) = I \delta(x)$$

where $J(x)$ is the charge current in the wire and I is the current in the electrode,

$$J(x) = -\sigma_D \frac{1}{2} \int d\omega \tilde{d}_\omega(x) \partial_x F_s^T - \sigma_D \frac{1}{2} \int d\omega n_\omega(x) \partial_x \varphi F_s^L \quad (\text{C15})$$

$$I = R_b^{-1} \frac{1}{2} \int d\omega N_\omega(x) [n_T - F_s^T - P F_t^T] \quad (\text{C16})$$

Here $\sigma_D = DN_F$ is the Drude conductivity and $R_b = (2e^2 \lambda N_F)^{-1}$ is the contact resistance.

2. Electric spin injection in normal metal

Before considering the superconducting case, let us check the injection in the normal state. In this case, $d_\omega = \tilde{d}_\omega = N_\omega = 1$, and $j_{x,\omega} = 0$, and the T - and L -channels fully decouple. The equations for the distributions functions F_s^T and F_t^T , Eqs. (C6-C8) simplify as,

$$-D\partial_x^2 F_s^T = 2\lambda \delta(x) [n_T - F_s^T - P F_t^T] \quad (\text{C17})$$

$$-D\partial_x^2 F_t^T + \frac{1}{\tau_s} F_t^T = 2\lambda \delta(x) [P (n_T - F_s^T) - F_t^T] \quad (\text{C18})$$

One can integrate these equations over the energy to get a closed system of equations for the charge and spin chemical potentials,

$$\mu = \frac{1}{2} \int F_s^T(\omega) d\omega \quad (\text{C19})$$

$$\eta = \frac{1}{2} \int F_t^T(\omega) d\omega \quad (\text{C20})$$

By multiplying Eqs. (C17)-(C18) with $\frac{1}{2}e^2 N_F$ and integrating over ω , we get

$$-\sigma_D \partial_x^2 \mu(x) = 2e^2 N_F \lambda [V - \mu(0) - P\eta(0)] \delta(x) \quad (\text{C21})$$

$$-\sigma_D \partial_x^2 \eta(x) + \sigma_D \kappa_s^2 \eta(x) = 2e^2 N_F \lambda [P (V - \mu(0)) - \eta(0)] \delta(x) \quad (\text{C22})$$

Equation (C21) is the charge continuity equation. The coefficient in front of the delta-function in its r.h.s. is the charge current flowing from the F-electrode and $2e^2 N_F \lambda = R_b^{-1}$ is identified with the inverse boundary resistance of the contact. Thus, from Eq.(C19) we get the Ohm's law relating the current through the contact with F-electrode to the voltage drop across the contact,

$$R_b I = V - \mu(0) - P\eta(0) \quad (\text{C23})$$

Finally, by expressing the source in Eg.(C22) in terms of the current I , the spin diffusion equation reads:

$$-\sigma_D \partial_x^2 \eta(x) + \sigma_D \kappa_s^2 \eta(x) = [PI - R_b^{-1} (1 - P^2) \eta(0)] \delta(x) \quad (\text{C24})$$

Eqs.(C24)-(C23) coincide in form with the equations used in the literature^{12,38,39} This equations are valid in the tunneling contact limit. In the case of transparent interfaces, in the source term in Eq.(C24) one should replace R_b by the resistance of the ferromagnet $R_s^F = l_s^F / \sigma_F$ ³⁸. In fact, the inverse of the total resistance should enter the second (back flow) term in the r.h.s. in Eq.(C24). In our case, $R_b \gg R_s^F$, the large interface resistance suppresses the back flow, while the source term, is determined by the current, does not depend on the transmission of the contact.

3. Electric spin injections in a superconductor: Linear regime

The situation when L- and T-channels decouple in general is the linear response to the voltage bias V . In this case,

$$n_T = \frac{1}{2} \left[\tanh\left(\frac{\omega + V}{2T}\right) - \tanh\left(\frac{\omega - V}{2T}\right) \right] \approx \frac{V}{2T \cosh^2\left(\frac{\omega}{2T}\right)}$$

$$n_L = \frac{1}{2} \left[\tanh\left(\frac{\omega + V}{2T}\right) + \tanh\left(\frac{\omega - V}{2T}\right) \right] = \tanh\left(\frac{\omega}{2T}\right) + O(V^2)$$

Using these equalities and inspecting Eqs.(C6)–(C9), (C11) and (C13) one finds that

$$F_{s,t}^T = O(V), \quad j_{x,\omega} = O(V),$$

$$F_s^L = \tanh\left(\frac{\omega}{2T}\right) + O(V^2), \quad F_t^L = +O(V^2)$$

Therefore the coupling can be neglected and the kinetic equations in the T-channel, read

$$-D\partial_x \left(\tilde{d}_\omega \partial_x F_s^T \right) + \frac{\Delta}{2} \text{tr} \{ \tau_1 (g^R + g^A) \} F_s^T = 2\lambda N_\omega \delta(x) [n_T - F_s^T - P F_t^T] \quad (\text{C25})$$

$$-D\partial_x (d_\omega \partial_x F_t^T) + \frac{d_\omega}{\tau_s} F_t^T = 2\lambda N_\omega \delta(x) [P (n_T - F_s^T) - F_t^T] \quad (\text{C26})$$

where in the r.h.s. $n_T = \frac{V}{2T \cosh\left(\frac{\omega}{2T}\right)}$. At $T \rightarrow 0$ only $\omega = 0$ contribution is relevant and this system of equations possesses a complete analytic solution.

a. Solution of the injection problem

In general, the solution to Eq.(C26) can be constructed in the same way as for the case of the spin-biased electrode. In fact, Eq.(C26) can be obtained from (B10) by the replacement $n_T \rightarrow P (n_T - F_s^T)$ in the r.h.s. Therefore solution of Eq.(C26) is immediately obtained from (B31),

$$F_t^T(x) = \frac{\lambda N_\omega(0) P (n_T - F_s^T(0))}{D d_\omega(0) \varkappa_t(\omega) + \lambda N_\omega(0)} e^{-\varkappa_t(\omega)|x|} \quad (\text{C27})$$

By inserting this result into the r.h.s. of (C25) we get a closed equation for the singlet distribution function F_s^T which determines the charge imbalance,

$$-D\partial_x \left(\tilde{d}_\omega \partial_x F_s^T \right) + \frac{\Delta}{2} \text{tr} \{ \tau_1 (g^R + g^A) \} F_s^T$$

$$= 2\lambda N_\omega \frac{D d_\omega(0) \varkappa_t(\omega) + (1 - P^2) \lambda N_\omega(0)}{D d_\omega(0) \varkappa_t(\omega) + \lambda N_\omega(0)} (n_T - F_s^T) \delta(x) \quad (\text{C28})$$

In this equation, in contrast to Eq.(C26), the coefficients in the l.h.s. are never small, even at $\lambda \rightarrow 0$ (\tilde{d}_ω is of order unity at $\omega = 0$). Therefore in the tunneling contact limit, *i.e.* large R_b (small λ), the r.h.s. can be treated as a perturbation. This means that $F_s^T(0)$ can be neglected compared to n_T both in the r.h.s. of Eq.(C28) and in the r.h.s. of Eq.(C27). In this regime we can relate the current I and the voltage V in the injector simply by integrating the r.h.s. of Eq.(C28) over ω ,

$$R_b I = \frac{V}{2} \int d\omega N_\omega(0) \frac{D d_\omega(0) \varkappa_t(\omega) + (1 - P^2) \lambda N_\omega(0)}{2T \cosh^2\left(\frac{\omega}{2T}\right) [D d_\omega(0) \varkappa_t(\omega) + \lambda N_\omega(0)]} \quad (\text{C29})$$

This relation can be written compactly as

$$V = R_{inj} I \quad (\text{C30})$$

where the effective resistance of the injector is

$$R_{inj}^{-1} = \frac{R_b^{-1}}{2} \int d\omega N_\omega(0) \frac{D d_\omega(0) \varkappa_t(\omega) + (1 - P^2) \lambda N_\omega(0)}{2T \cosh^2\left(\frac{\omega}{2T}\right) [D d_\omega(0) \varkappa_t(\omega) + \lambda N_\omega(0)]} \quad (\text{C31})$$

At the same level of accuracy the injected spectral spin reads,

$$S_\omega(x) = N_\omega(x)F_t^T(x) = PI \frac{R_{inj}\lambda N_\omega^2(0)e^{-\sqrt{\varkappa_\omega^2 + \varkappa_s^2}|x|}}{2T \cosh^2\left(\frac{\omega}{2T}\right) [Dd_\omega(0)\varkappa_t(\omega) + \lambda N_\omega(0)]} \quad (C32)$$

b. Detection of the injected spin by magnetic detector

Similarly to the spin-bias case in Sec.2.4, the voltage V_d induced in the detector is calculated by setting to zero the detector current

$$I_d \sim \int d\omega [N_\omega(x_d)n_T(V_d) - N_\omega(x_d)F_s^T(x_d) - P_d S_\omega(x_d)] = 0$$

The important difference with Eq.(B43) for the spin-biased case is the presence of the charge imbalance component, F_s^T , at the location of detector. This contribution is eliminated by subtracting the V_d measured for parallel and antiparallel orientations of the injector and detector polarizations, that is, $V_d^{\uparrow\uparrow}$ for $P_d = P$, and $V_d^{\uparrow\downarrow}$ for $P_d = -P$. This is how non-local spin valves are operated^{35,38} The corresponding nonlocal resistance then reads,

$$R_{NL} = \frac{V_d^{\uparrow\uparrow} - V_d^{\uparrow\downarrow}}{I} = 2P \frac{\int d\omega S_\omega(x_d)}{I \int \frac{N_\omega(x_d)d\omega}{2T \cosh^2\left(\frac{\omega}{2T}\right)}} \quad (C33)$$

By inserting here Eqs.(C32) and (C31) we get explicitly,

$$R_{NL} = R_b P^2 \frac{\int \frac{\lambda N_\omega^2(0)e^{-\sqrt{\varkappa_\omega^2 + \varkappa_s^2}x_d} d\omega}{2T \cosh^2\left(\frac{\omega}{2T}\right) [Dd_\omega(0)\varkappa_t(\omega) + \lambda N_\omega(0)]}}{\left[\int \frac{N_\omega(0)[Dd_\omega(0)\varkappa_t(\omega) + (1-P^2)\lambda N_\omega(0)]d\omega}{4T \cosh^2\left(\frac{\omega}{2T}\right) [Dd_\omega(0)\varkappa_t(\omega) + \lambda N_\omega(0)]} \right] \left[\int \frac{N_\omega(0)e^{-\varkappa_\omega x_d} d\omega}{4T \cosh^2\left(\frac{\omega}{2T}\right)} \right]} \quad (C34)$$

where $R_b = (2e^2\lambda N_F)^{-1}$. This equation is used to plot R_{NL} in the Fig. 2 (d) of the main text.

In the limit $T \rightarrow 0$ we have $\frac{1}{2T \cosh^2(\omega/2T)} \rightarrow 2\delta(\omega)$ and the above expression simplifies dramatically,

$$R_{NL} = R_b P^2 \frac{2\lambda e^{-\varkappa_t x_d}}{Dd_0(0)\varkappa_t + (1 - P^2)\lambda N_0(0)} \quad (C35)$$

where $\varkappa_t = \sqrt{\varkappa_0^2 + \varkappa_s^2} - \varkappa_0$. From here the normal state result is obtained by setting $d_0 = N_0 = 1$ and $\varkappa_t = \varkappa_s$, whereas in the superconductor $d_0(0) = N_0^2(0)$ with $N_0(0) = \tilde{\lambda} = \lambda\xi_0/D = \frac{1}{2}\rho_D\xi_0/R_b$ (here $\rho_D = 1/\sigma_D$ is the Drude resistivity).

Appendix D: Spin-to-charge conversion: Spin-galvanic effect

Once we understood that spin can be injected even for voltages below the gap, we focus now on the spin-charge conversion via the spin-galvanic effect. For this we assume a sizable spin-orbit coupling in the superconductor. Moreover, because of its closer connection with experiments involving tunneling barriers, we assume here that $\eta/\Delta > \tilde{\lambda}$, such that the spectral functions of the superconductor, at zeroth order in the spin-galvanic parameter γ , are those given in Section B 3.

We treat the problem perturbatively in the spin-galvanic coefficient γ^7 . The generated triplet GF now works as a perturbation in the singlet channel,

$$-D\check{g}_0 \left(\partial_x^2 \check{g}_{1s} - i\partial_x^2 \theta[\tau_3, \check{g}_0] \right) + [-i\omega\tau_3 + \Delta\tau_1, \check{g}_{1s}] = -\partial_x (\gamma\check{g}_t)$$

Importantly, the presence of the τ_1 component in the Keldysh source inevitably generates the τ_2 component in the Keldysh GF, which then breaks the continuity equation. To restore the charge conservation we are forced to introduce a superconducting phase θ by $\check{g} \mapsto e^{-i\tau_3\theta}\check{g}e^{i\tau_3\theta}$, determined from the condition

$$\int \frac{d\omega}{2\pi} \text{tr} \{ \tau_2 g^K(\omega) \} = 0 \quad (D1)$$

which ensures that there is no imaginary correction to Δ , and thus guaranties the charge conservation. The correction, g_1^R , to the retarded GF is determined from the equation,

$$-Dg_0^R\partial_x^2g_1^R + [-i\omega\tau_3 + \Delta\tau_1, g_1^R] = -iD\partial_x^2\theta g_0^R[\tau_3, g_0^R],$$

which is readily solved in the Fourier space,

$$g_1^R = \frac{iDq^2\theta_q}{Dq^2 + 2\Omega_R}[\tau_3, g_0^R] \quad (\text{D2})$$

Similarly we find the advanced component.

The Keldysh component of the above equation reads,

$$\begin{aligned} -D(g_0^R\partial_x^2g_{1s}^K + g_0^K\partial_x^2g_1^A) + [-i\omega\tau_3 + \Delta\tau_1, g_{1s}^K] = & -\partial_x(\gamma g_t^K) \\ & -iD\partial_x^2\theta(g_0^R[\tau_3, g_0^K] + g_0^K[\tau_3, g_0^A]) \end{aligned} \quad (\text{D3})$$

It is convenient to write this equation using the standard representation of g^K in terms of the distribution function³⁴,

$$g^K = g^R F - F g^A = g_0^K + (g_1^R - g_1^A)h_0 + (g_0^R\tau_3 - \tau_3g_0^A)h_{1T},$$

where the distribution function has the form, $F = h_0 + \tau_3 h_{1T}$ with $h_0 = \tanh \frac{\omega}{2T}$. Thus, from Eq. (D3) we find the equation for the non-equilibrium part of the distribution function,

$$-D(\tau_3 - g_0^R\tau_3g_0^A)\partial_x^2h_{1T} + [-i\omega\tau_3 + \Delta\tau_1, g_0^R\tau_3 - \tau_3g_0^A]h_{1T} = -\partial_x(\gamma g_t^K), \quad (\text{D4})$$

which can be further simplified,

$$(\tau_3 - g_0^R\tau_3g_0^A)\{-D\partial_x^2h_{1T} + (\Omega_R + \Omega_A)h_{1T}\} = -\partial_x(\gamma g_t^K) \quad (\text{D5})$$

Notice that the matrix structure on either side of this equation is identical, which confirms the ansatz for the distribution function. The explicit solution takes the form,

$$h_{1T} = \gamma \frac{-iq2\lambda_q\tau_s n_T(\omega)}{[Dq^2 + \Omega_R + \Omega_A][1 + \tau_s(\Omega_R + \Omega_A) + l_s^2q^2]} \quad (\text{D6})$$

1. Charge imbalance and the voltage drop

The induced distribution function h_{1T} determines the charge imbalance induced in the superconductor,

$$Q_q^* = \frac{\pi\nu}{4} \int \frac{d\omega}{2\pi} \text{tr} \{g^K(\omega)\} = \frac{\nu}{2} \int d\omega N_0(\omega) h_{1T} = \gamma \frac{\nu\lambda_q\tau_s}{iDq(1 + l_s^2q^2)} \int d\omega N_0(\omega) n_T(\omega)$$

and the potential drop across the injector,

$$e\Delta\varphi = i \lim_{q \rightarrow 0} q Q_q^* = \gamma \frac{\nu\lambda\tau_s}{D} \int d\omega N_0(\omega) n_T(\omega) \quad (\text{D7})$$

Notice that at $T \rightarrow 0$ and $V_s < \Delta$ no charge imbalance and no voltage drop (larger than η) is induced from the injected spin. In this situation only a supercurrent and or a phase drop are expected.

2. Phase gradient and the phase drop

The phase gradient is determined by the condition, Eq(D1),

$$\int \frac{d\omega}{2\pi} \text{tr} \{\tau_2 g_{1s}^K\} = \int \frac{d\omega}{2\pi} \text{tr} \{\tau_2(g_1^R - g_1^A)h_0 + \tau_2(g_0^R\tau_3 - \tau_3g_0^A)h_{1T}\} = 0$$

or, equivalently, by the requirement that the continuity equation is fulfilled,

$$\partial_x j(x) = 0$$

where the current is defined as follows,

$$\begin{aligned}
j &= -\frac{\pi N_F}{2} D \int \frac{d\omega}{2\pi} \text{tr} \left\{ \tau_3 [\check{g} \partial_x \check{g} - i \partial_x \theta \check{g} [\tau_3, \check{g}]]^K \right\} + \frac{\pi N_F}{2} \int \frac{d\omega}{2\pi} \text{tr} \left\{ \tau_3 \gamma g_t^K \right\} \\
&= -\frac{N_F}{4} D \partial_x \int d\omega \text{tr} \left\{ (1 - \tau_3 g_0^R \tau_3 g_0^A) h_{1T} + h_0 \tau_3 [g_0^R (g_1^R - i\theta[\tau_3, g_0^R]) - g_0^A (g_1^A - i\theta[\tau_3, g_0^A])] \right\} \\
&\quad + \frac{N_F}{4} \int d\omega \text{tr} \left\{ \tau_3 \gamma g_t^K \right\}
\end{aligned}$$

With the solutions for $g_1^{R,A}$ and h_{1T} from Eqs. (D2,D6), the Fourier component of the current is given by

$$\begin{aligned}
j_q &= \gamma \frac{N_F}{2} \int d\omega \frac{\Omega_R + \Omega_A}{Dq^2 + \Omega_R + \Omega_A} s_q(\omega) \\
&\quad + q\theta_q \frac{\sigma_0}{4} \int d\omega h_0(\omega) \left[\frac{\Omega_R}{Dq^2 + \Omega_R} \text{tr} \left\{ \tau_3 g_0^R [\tau_3, g_0^R] \right\} - \frac{\Omega_A}{Dq^2 + \Omega_A} \text{tr} \left\{ \tau_3 g_0^A [\tau_3, g_0^A] \right\} \right].
\end{aligned}$$

which after evaluation of the traces result in,

$$j_q = \gamma \frac{N_F}{2} \int d\omega \frac{\Omega_R + \Omega_A}{Dq^2 + \Omega_R + \Omega_A} s_q(\omega) - iqK_s(q)\theta_q \quad (\text{D8})$$

where we have introduced a q -dependent superfluid weight,

$$\begin{aligned}
K_s(q) &= -i\sigma_0 \int d\omega \left\{ \frac{\Delta^2}{(Dq^2 + \Omega_R)\Omega_R} - \frac{\Delta^2}{(Dq^2 + \Omega_A)\Omega_A} \right\} \tanh \frac{\omega}{2T} \\
&= 4\pi\sigma_0 T \sum_{\omega_n} \frac{\Delta^2}{\left(Dq^2 + \sqrt{\Delta^2 + \omega_n^2} \right) \sqrt{\Delta^2 + \omega_n^2}}
\end{aligned}$$

The phase θ is determined by the condition $\partial_x j(x) = 0$, which requires $j(x) = \text{const}$. The constant depends on the geometry and boundary conditions. There are two relevant situations, sketched in Fig. 1(c-d) of the main text and which we analyze next.

I. Wire with open boundaries (Fig. 1c in main text) : In this case the current should be identically zero $j(x) = 0$ which determines the phase distribution,

$$iqK_s(q)\theta_q = \gamma N_F \int_0^\infty d\omega \frac{\Omega_R + \Omega_A}{Dq^2 + \Omega_R + \Omega_A} s_q(\omega)$$

For the induced anomalous phase drop across the injector we get depending of the wire length L ,

$$\delta\theta = i \lim_{q \rightarrow 0} q\theta_q = \begin{cases} \frac{\gamma}{K_s} N_F \int_0^\Delta d\omega s_{q=0}(\omega) = \frac{\gamma}{K_s(0)} S_\Delta, & L < \Lambda_{Q^*} \\ \frac{\gamma}{K_s} N_F \int_0^\infty d\omega s_{q=0}(\omega) = \frac{\gamma}{K_s(0)} S, & L > \Lambda_{Q^*} \end{cases}$$

where Λ_{Q^*} is the charge imbalance length¹⁸. Formally, the first case corresponds to taking the limit $\eta \rightarrow 0$ before the limit $q \rightarrow 0$, and the in the second case one takes $q \rightarrow 0$ first while keeping η finite.

II. Closed loop geometry (Fig. 1d in main text): In this case the current $j(x) = I$ induced in the loop is given by the $q = 0$ component of the current density Eq. (D8) under the condition of regularity and periodicity of the phase, $I \cdot L = j_{q=0}$, which implies,

$$I = \frac{\gamma}{L} N_F \int_0^\infty d\omega s_{q=0}(\omega) = \frac{\gamma}{L} S \quad (\text{D9})$$

The total current is thus given by the total injected spin divided by the loop length. This is the same as in the normal state, but the current is larger, because the injected spin is larger in the superconducting case, and part of it is superfluid. The distribution of the supercurrent along the loop is readily found as,

$$j_s(q) \equiv iq\kappa_s(q)\theta_q = \gamma N_F \int_0^\infty d\omega \frac{Dq^2}{Dq^2 + \Omega_R + \Omega_A} s_q(\omega) \quad (\text{D10})$$

We have ignored the magnetic field induced by the current, assuming that the current is small compared to the critical current.
